Acral reed nevus with parallel ridge pattern: an exception to the rule of malignancy*

Dear Editor,

Reed nevi (RN) are almost exclusively junctional neoplasms distinguished as a variant of Spitz nevus (SN) by their significant melanogenesis and growth pattern. Acral presentation of SN is rare and has specific clinical and histopathological features.¹ Nonetheless, dermoscopic findings of SN and its variants on the acral skin are poorly documented.² Herein we describe a case of RN on the volar skin of a finger in which parallel ridge pattern was observed by dermoscopic examination.

A 9-year-old boy presented with an asymptomatic pigmented lesion on his right hand. He had detected the lesion 8 months previously and had enlarged gradually. He had no personal or family history of malignant tumors. Physical examination revealed an asymmetrical dark brown macule, 13×3 mm in size, located on the volar region of the second right finger. The lesion exhibited an atypical linear morphology similar to a crescent moon (Fig. 1A). Dermoscopic findings showed a brownish parallel ridge pattern with some streaks at the periphery (Fig. 1B). A complete surgical excision was done to rule out malignancy. Histological examination revealed several small nests, vertically oriented, composed of heavily pigmented spindled melanocytes along the dermo-epidermal junction (Fig. 1C-D). No melanocytes were seen in the dermis. A diagnosis by an RN was done.

Acral SNs understood by those located on soles, palms and fingers are infrequent, being reported to comprise less than 2% of all SNs.¹ They are more common in young female adults, more frequently located on the feet, and larger than acral melanocytic nevi.¹ Acral RN or "pigmented spindle-

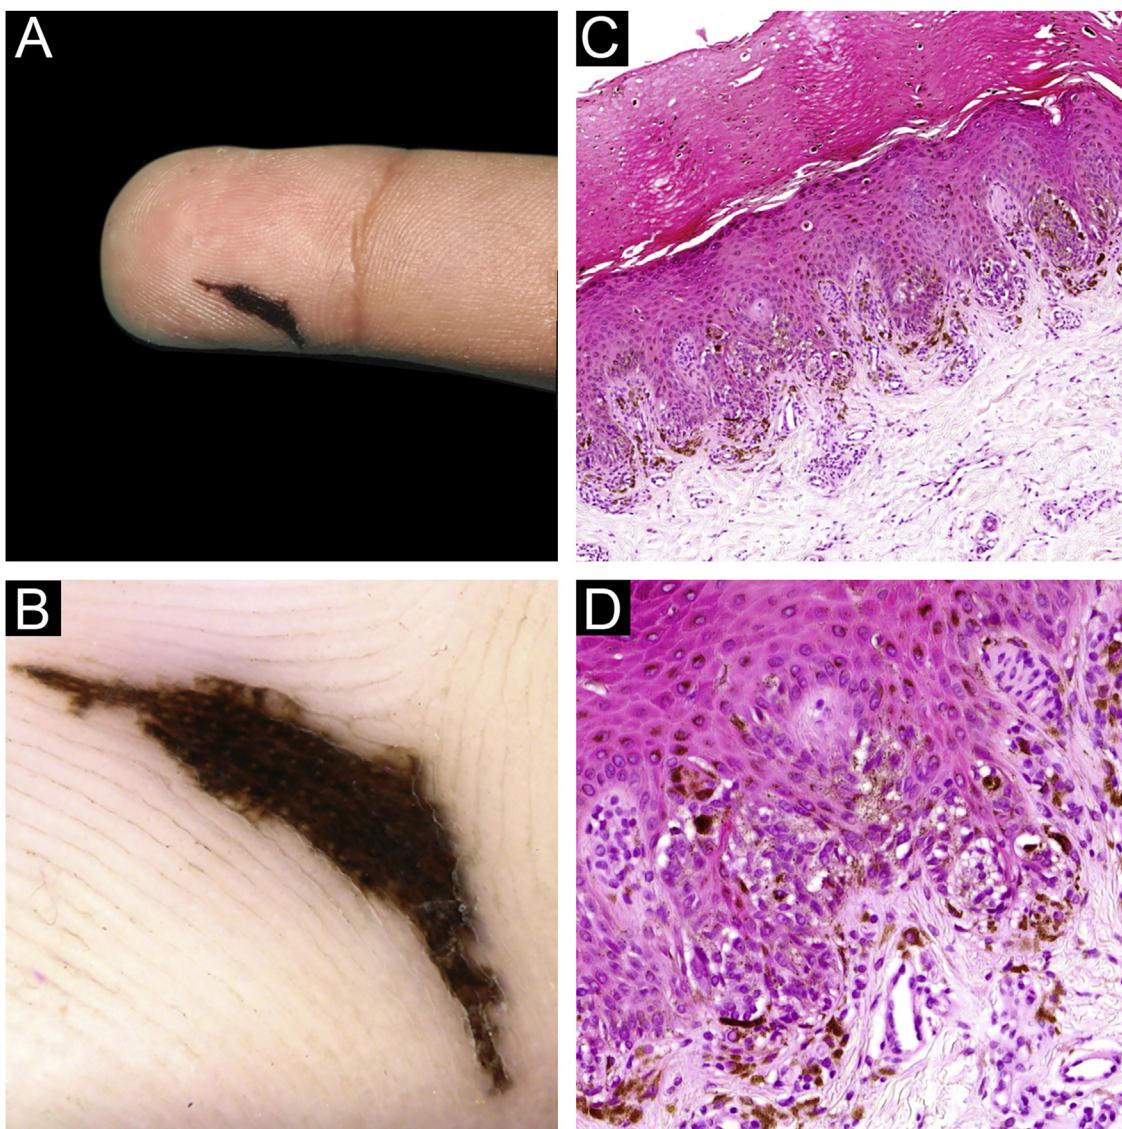

Figure 1 Reed nevus on the finger (A) Clinical features of the lesion. (B) Dermoscopic findings show a parallel ridge pattern with some peripheral streaks. (C) Histopathological findings were tumor cell nests scattered within the epidermis (Hematoxylin & eosin, $\times 100$). (D) Junctional nests were composed of heavily pigmented spindle-shaped melanocytes, vertically oriented (Hematoxylin & eosin, $\times 200$).

cell nevus” is the most common variant of SN that typically presents as a heavily pigmented lesion.¹ Given the overlapping clinicopathologic features with malignancy, their clinical diagnosis is often of an atypical nevus or a malignant melanoma.^{1,2} Dermoscopic examination is useful in differentiating RN and acral lentiginous malignant melanoma.² Dermoscopic patterns most commonly associated with SN are starburst and globular patterns.² However, a characteristic pattern upon dermoscopic examination of SN localized on the glabrous skin has not been described.^{2,3} A review of the literature revealed only nine cases of acral SN and its variants with the dermoscopic examination.⁴ A parallel furrow pattern with peripheral dots, streaks, and projections and a starburst pattern has been reported in four and three cases, respectively.⁴ A crista-dotted pattern was described in one case of SN on the palm.³ Only Jurakić

et al. in 2018 reported a young female with a rapidly growing plantar pigmented SN that had a dermoscopic parallel ridge pattern with few peripheral globules, similar to our case.⁵

In conclusion, we report a case of an acral RN showing a parallel ridge pattern on dermoscopy, an exception to the rule of malignancy. The present report aims to highlight that, although such a pattern is highly suggestive of melanoma, it can also be seen in a proportion of acral SNs localized on the glabrous skin. However, an SN with asymmetry and/or atypical dermoscopic pattern is impossible to differentiate from melanoma and, thereby, must be excised irrespective of age or clinical morphology.

Bilateral giant Becker's nevus*

Dear Editor,

A 13-year-old boy presented with a 6-year history of multiple asymptomatic brown macules affecting the chest and scapular regions bilaterally. The pigmentation gradually darkened and progressively involved the neck, right forearm, both shoulders, upper arms, and axillae (Figs. 1 and 2). Increased hairs were observed on the lesions. No other accompa-

nied abnormality of the skin or musculoskeletal system was found. Familial and medical histories were unremarkable. Laboratory investigations including complete blood cell count, liver, and renal function were all normal. Radiography of the chest, spine and upper extremities also showed no abnormality. The histopathological examination revealed slight hyperkeratosis, with acanthosis, elongation, and fusion of the epidermal ridges and hyperpigmentation of the basal layer (Fig. 3). These features were suggestive of Becker's nevus.

Becker's nevus is a type of epidermal nevus, characterized by a single hyperpigmented patch with or without hypertrichosis, and predominantly involves the unilateral upper trunk, scapular region, or upper arm unilaterally, the
