

Ecology of *Phallotorynus pankalos* (Cyprinodontiformes: Poeciliidae) in a first-order stream of the upper Paraná Basin

Yzel R. Súarez, João Paulo da Silva, Lilian P. Vasconcelos
and William Fernando Antonialli-Júnior

Some aspects of the population ecology of *Phallotorynus pankalos* in a first-order stream of the Iguatemi River Basin are described based on samples taken from March/2007 to February/2008. A total of 2680 individuals, including 948 males and 1732 females was collected. Adult females are larger than males; theirs mean fecundity was estimated as 6.5 embryos/female. There was a strong correlation between standard length and ovary weight, relative ovary weight, and number of embryos. The size of the first maturation of 50% of female population was estimated as 18.24 mm of standard lenght. High female mortality was observed after the first reproduction and sex ratio presents seasonal variation with higher female proportion in the winter.

Para descrever alguns aspectos da ecologia populacional de *Phallotorynus pankalos* em um riacho de primeira ordem da bacia do rio Iguatemi foram realizadas amostragens de março/2007 a fevereiro/2008. Um total de 2680 indivíduos, distribuídos em 948 machos e 1732 fêmeas, foi coletado. Fêmeas adultas foram maiores que os machos e sua fecundidade média foi estimada em 6,5 embriões/fêmea. Foi observada forte correlação entre o comprimento padrão e o peso dos ovários, peso relativo dos ovários e número de embriões. O tamanho da primeira maturação de 50% da população de fêmeas foi estimado em 18,24 mm de comprimento padrão. Observamos elevada mortalidade de fêmeas após a primeira reprodução e variação sazonal na proporção sexual, com maior proporção de fêmeas no inverno.

Key words: Fecundity, Iguatemi River Basin, Population ecology, Reproduction, Stream fish.

Introduction

Poeciliid fishes are widely distributed, with more than 300 species (Lucinda, 2003), occurring mainly in shallow waters being one of the dominant species in some regions, such as the Central America. Their flexibility in diet, life-history strategies and their ability to survive and reproduce under hypoxic conditions may have facilitated the exploitation of diverse habitats (Chapman, 1992).

Many studies have focused on evolutionary aspects of poeciliid species (Hendler, 1980; Hendler, 1983; Magurran *et al.*, 1995; Langerhans, 2004). Some have treated morphological description and comparison of the sexes (Gusmão & Pavanelli, 1996). Others have suggested that some species can be used to assess habitat integrity (Bozzetti & Schulz, 2004; Cunico *et al.*, 2006; Ferreira & Casatti, 2006; Pinto *et al.*, 2006; Vieira & Shibatta, 2007), mainly *Poecilia reticulata* and *Phalloceros caudimaculatus*.

Population studies of poeciliid species are rare in Brazil. Among these are the studies of Machado *et al.* (2002) and Wolff *et al.* (2007) on the reproductive cycle and population

biology of *Phalloceros caudimaculatus* (probably *Phalloceros harpagos* - see Lucinda, 2008) in upper Paraná Basin in São Paulo and Paraná States, respectively, and the study of Casatti *et al.* (2006) on the reproductive biology of *Pamphorichthys hollandi* in the upper Paraná Basin.

The genus *Phallotorynus* includes small poeciliid species, endemic to South America in drainages of the Paraíba do Sul, Paraná and Paraguay rivers. The species of this genus are poorly studied from the ecological viewpoint. However, taxonomic, systematic and descriptive studies of coloration, behavior, and morphology have been published. *Phallotorynus pankalos* was described based on few individuals sampled in Sossego stream in Iguatemi River Basin (Lucinda *et al.*, 2005).

The present study aimed to gather initial population information for *Phallotorynus pankalos*, in a first-order stream of the Iguatemi River Basin, answering the following questions: (1) How much do the sexes differ in the weight-length relationship? (2) What is the size at first sexual maturation in females? (3) Is there a relationship between the female standard length and the sexual investment?

Material and Methods

Study site

The Iguatemi River Basin is strongly impacted by human actions, presenting high levels as deforestation and siltation in the major portion, principally by agricultural activities. The Iguatemi River is approximately 300 km long and located in the upper Paraná River basin in Mato Grosso do Sul State. There is a wide floodplain and marginal lakes in the lower parts of the basin. The middle stretch has a small floodplain and some marginal lakes with little connection with the river.

The predominant vegetation is the Cerrado, altering with semideciduous seasonal forest. The juncture of Iguatemi River with the Paraná River is located at an altitude of 226 m, approximately 20 km from Sete Quedas Falls, an important biogeographical barrier now submerged by the Itaipu Reservoir.

Farming and ranching are the main economic activities. The Brazilian part of the area was logged intensively in the past, and timber extraction is still occurring in Paraguay. Together, deforestation and agriculture are causing siltation in much of the Iguatemi basin.

Field and laboratory methods

The fish samples were taken from March/2007 to February/2008 at three sites in the Iguatemi River Basin. However, we analyzed the fish from only one site (Sossego Stream) located at 23°38'41.4"S 55°12'5.1"W, due to low catches at the other locations (Fig. 1). The samples were taken during daylight, with a rectangular 1.2 x 0.8 m sieve, with 2 mm mesh size. Specimens were fixed in 10% formalin and preserved in 70% ethanol for biometric data measurement: length standard (LS), total weight (TW) and sex. Voucher individuals

were deposited at the Coleção de Peixes of Universidade Estadual de Maringá (20 individuals - NUP 5839).

Data analysis

A Kolmogorov Smirnov test was used in order to compare length and weight distribution between sexes because the criteria for normality were not met, even after logarithmic transformation. This procedure was adopted for standard length classes of 2 mm and with relative abundance of males and females in each class. The length-weight relationships for each sex were obtained by non-linear regression.

For 35 females in final development stage of embryos, the ovary weight and relative ovary weight (ovary weight/total weight) were obtained. The number of embryos was obtained for 59 females and correlated (Pearson's r) with standard length, to assess the influence of female size on sexual investment. For 17 females, embryos length and weight were obtained and also correlated with female standard length.

The probability of female maturation was obtained using logistic regression, when the presence of eggs or embryos was used to define if the individuals are reproductive. Standard length was used as the explanatory variable, according to Roa *et al.* (1999). Then we estimated the size of first maturation of 50% of female population ($LS_{50\%}$) and 100% of female population ($LS_{100\%}$). The sex ratio (number of females per male) was calculated monthly and the chi-square (χ^2) test, with Yates correction was used to verify differences in sex ratio.

Results

A total of 2680 individuals of *Phallotorynus pankalos* were analyzed, including 948 males (35.4%) and 1732 females (64.6%). The maximum standard length of males was 22.3 mm

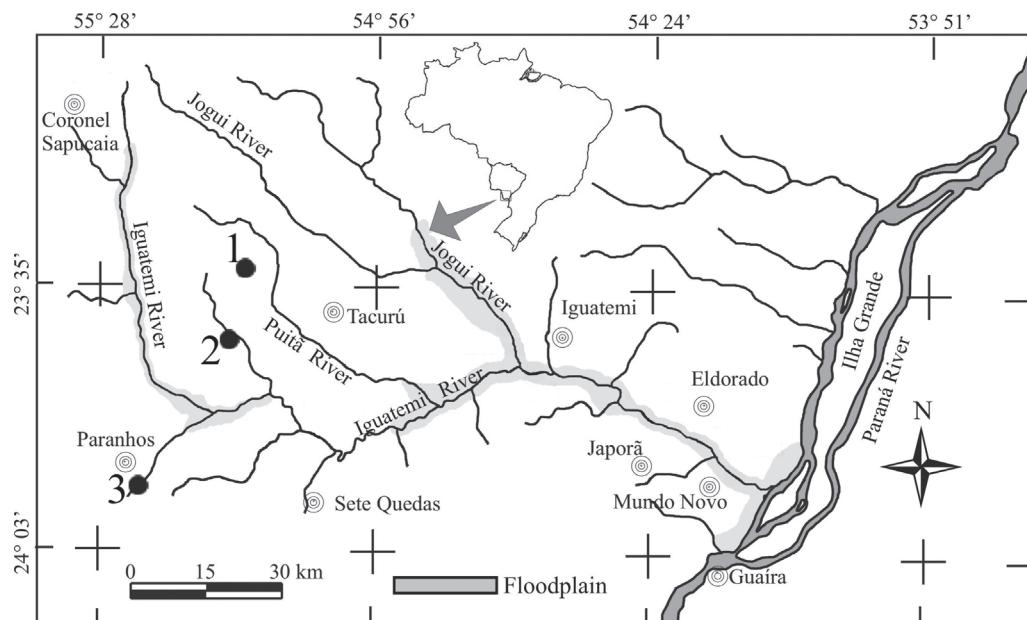

Fig. 1. Locations of the sampling sites with where *Phallotorynus pankalos* was recorded in the Iguatemi River Basin, upper Paraná River. 1- Sossego Stream; 2- Mirim Stream and 3- Piraí Stream.

(median = 17.2 mm) and for females was 37.2 mm (median = 18 mm) (Fig. 2). The maximum total weight for males was 0.235 g (median = 0.092 g) and for females was 1.298 g (median = 0.112 g). We observed that the Total weight distribution differ between sexes ($P = 0.013$), however the Standard length (LS) did not differ between sexes ($P = 0.097$) (Fig. 2).

The length-weight relationship showed a larger increase of weight in females compared to males. Females showed an angular coefficient higher than 3, however males presented angular coefficient smaller than 3 (Table 1 and Fig. 3).

The mean number of embryos of reproductive females was estimated at 6.5, ranging from 2 to 16 embryos. The relative ovary weight ranged from 5.3% to 26.4%. We found a significant influence of standard length of females on number of embryos ($r = 0.788$; $P = 0.000$) and ovary weight ($r = 0.829$; $P = 0.000$). However, for relative ovary weight the correlation was marginally significant ($r = 0.394$; $P = 0.058$), when with increasing size, investment in reproduction increased (Fig. 4). There was no significant correlation between the number of embryos and the mean total length of embryos ($r = 0.102$; $P = 0.696$) and also between the number of embryos

and the mean weight of embryos ($r = -0.223$; $P = 0.389$) i.e., the increase in number of embryos did not result in a decrease in embryo size (Fig. 5). We estimated that the size at first maturation of 50% of the female population was 18.2 mm, and that of 100% of the female population was 25.6 mm (Fig. 6).

The mean total size of embryos in final development stage was estimated at 6.18 mm ($sd = 0.55$), weighting 0.006 g ($sd = 0.001$). Embryo weight was significantly correlated with embryo size ($r = 0.593$; $P = 0.012$) (Fig. 7). However, no correlations were observed between female standard length and embryo size ($r = 0.287$; $P = 0.265$) and weight ($r = -0.142$; $P = 0.588$) (Fig. 8). The size of embryos represented approximately 28.4% of female standard length.

The sex ratio was 1.82 females per male during the whole sampling period, and it varied seasonally ($\chi^2 = 175.67$; $P < 0.000$) with higher values during winter, with 5.64 females by males in July (Fig. 9). Using the length frequency of females, we calculated that only 47.8% of females reached a size above LS_{50%}, and only 6.4% of females reached a size above LS_{100%}, suggesting high mortality after the first reproduction. In the laboratory, we observed that after reproducing, females had

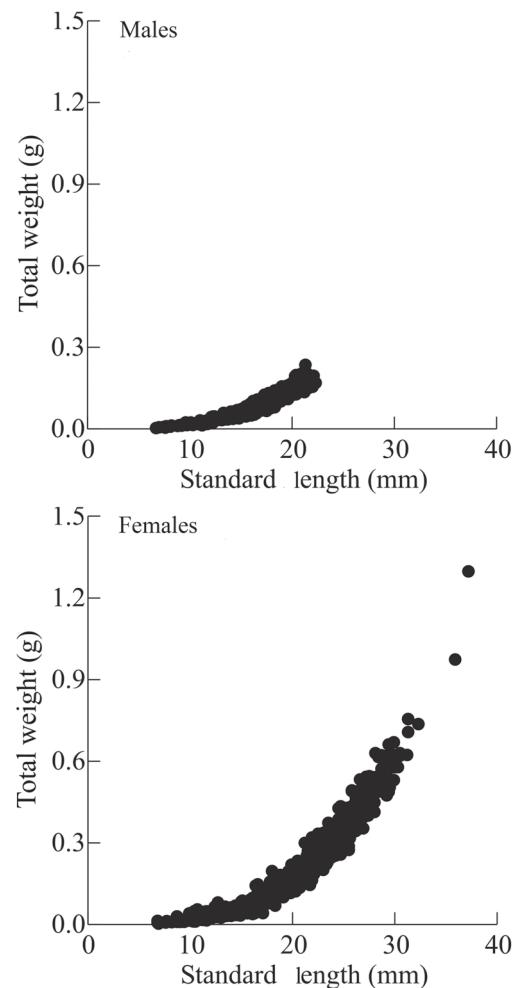

Fig. 3. Length-weight relationships for males and females of *Phallotorynus pankalos* in a first-order stream of the Iguatemi River Basin from March/2007 to February/2008.

Table 1. Non-linear regression of length-weight relationships for *Phallotorynus pankalos* in a first-order stream of the Iguatemi River Basin. Estimated parameters and confidence interval.

Sexes	Constant a	Angular coefficient b	r ²
Males	2.27 × 10 ⁻⁵ (1.85 × 10 ⁻⁶ to 2.68 × 10 ⁻⁵)	2.93 (2.86-2.99)	0.923
	8.52 × 10 ⁻⁶ (7.72 × 10 ⁻⁶ to 9.32 × 10 ⁻⁶)	3.29 (3.26-3.32)	
Females			0.967

greater difficulty in swimming, resulting in higher mortality, thus corroborating the length-frequency data.

Discussion

The observed maximum size for females was slightly larger than that found by Lucinda *et al.* (2005). The difference may be explained by the larger number of individuals analyzed, compared to the number of type specimens.

The larger weight increment as a function of length observed in females compared to males occurs because females invest more in growth than do males. This difference is common in poeciliids (Chapman, 1992; Machado *et al.*, 2002) and is interpreted as a strategy to maximize reproductive output (Keane & Neira, 2004) or influenced by a major weight of gonads in females (Wolff *et al.*, 2007).

The number of embryos observed in the females analyzed was small compared to that in *Phalloceros caudimaculatus*, with 12.5 embryos found by Machado *et al.*, (2002). This result can be explained by a larger proportional size of these embryos (28.4% of female standard length) found for *Phallotorynus pankalos*. The smaller number may be a function of the larger size of embryos, which may result in a higher probability of survival of the embryos.

The positive correlation of sexual investment and female size is in agreement with many studies on fish reproductive biology and sexual investment. Larger females can allocate more energy to their offspring (Casatti *et al.*, 2006; Mazzoni

& Silva, 2006; Mai *et al.*, 2007). However, the increase of embryo number with increase in female size reduces the survival probability of females; if the mean size of embryos is not reduced, then the large offspring of larger females may lead to death of the female.

Discussing population structure of *Poecilia gillii*, Chapman (1992) observed differences in sex ratios. In isolated pools, the sex ratios were approximately equal, whereas in streams the ratio was positively biased toward females, suggesting that differences in environmental characteristics and seasonally catastrophic mortality can affect the probability of survival, altering the sex ratio.

Despite the equal sex ratio at birth in poeciliid species, adult populations are positively biased toward females, because males suffer comparatively higher mortalities from predation, accelerated physiological aging, and stressors (Krumholz, 1948; Haynes & Cashner, 1995). *Gambusia holbrookii* had more than 5 females per male in some samples in Tasmanian streams (Keane & Neira, 2004). Bisazza *et al.*, (2000) observed that males of *Jenynsia multidentata* (Anablepidae) couple with females furtively and without their consent, and expend a large part of the day in this activity; this may make the males less careful compared to females in avoiding predator attacks, biasing the sex ratio toward females.

In our study, we observed a low probability of survival in females after they reached the size at which 100% of females are reproductive. This result may be influenced by higher predation pressure after female reproduction, interacting with lower tolerance to infections. In the laboratory, many females died even without predators, resulting in a balanced sex ratio. The clear seasonality in sex ratio can be a result of decrease of reproductive investment in winter, in response to environmental unfavorable conditions, conducting to smaller female mortality rates and proportionally increasing their abundance when compared to males, however, only with the analysis of seasonality in reproductive intensity and female mortalities can explain this pattern.

Concluding, the smaller fecundity observed for *P. pankalos*, associated to its restrict geographic distribution and higher

mortality rate for females after first reproduction can turn this species vulnerable to environmental degradation of its occurrence area (deforesting and siltation), reinforcing the need of other studies about its population ecology to propose policies for conservation of aquatic resources in this region.
