Abstract

Background: Indoor cycling is an aerobic exercise that employs large muscle groups of the lower limbs, lacking osteoarticular impact and high energy expenditure, which makes it interesting to generate a non-pharmacological strategy.

Objective: To assess body composition and lipid profile in overweight women after twelve weeks of low-calorie diet and indoor cycling training.

Methods: We randomly assigned 40 women (23.90 ± 3.10 years), divided into four groups: control (C), indoor cycling (CI), indoor cycling combined with low-calorie diet (CD) and low-calorie diet (D). The variables were: height and body mass, BMI, fat percentage, lean body mass, triglycerides, cholesterol and lipoproteins (HDL, LDL, VLDL). The indoor cycling training consisted of three weekly sessions of 45 minutes each and an energy restriction of about 1,200 kcal. The study lasted 12 weeks. We used descriptive statistics (mean and standard deviation) and inferential statistics (Student’s t test). The level of significance was p < 0.05.

Results: The groups CI, CD and D significantly reduced the mean anthropometric variables after 12 weeks of intervention (body mass, fat percentage and body mass index), and serum levels of total cholesterol and triglycerides. HDL cholesterol increased significantly for groups CI and CD.

Conclusion: According to the results, the indoor cycling and the low-calorie diet helped fight overweight and control serum lipids. (Arq Bras Cardiol 2010; 95(2): 173-178)

Key words: Overweight; bicycling; lipids; body composition.

Introduction

Dyslipidemia and obesity represent a serious public health problem and should be addressed through prevention programs and education. Treatment includes changes in lifestyle with healthy eating habits, maintenance or acquisition of adequate body mass, regular exercising and, depending on the response, the use of hypolipemiant agents³,4.

Regular exercising has received great reputation in the field of health, not just for its action alone in the prevention and control of cardiovascular diseases³,⁴ but also because it induces positive changes to the levels of plasma lipids³.

Several studies have shown that regular exercising may promote chronic effects such as decrease in serum triglycerides (TG), low density lipoprotein (LDL), total cholesterol (TC), insulin resistance, body mass (BM), body mass index (BMI), body fat percentage (BF%), as well as increased levels of high density lipoprotein (HDL), lean body mass (LBM) and basal metabolic rate⁶,⁷. The one that most works on the metabolism of lipoproteins is the aerobic exercise⁸.

Indoor cycling⁹ is an aerobic exercise that employs large muscle groups of the lower limbs, lacking osteoarticular impact and high energy expenditure, which makes it interesting to generate a non-pharmacological strategy. It applies to all ages and different fitness levels.

In a period of clear consolidation in the fitness industry, indoor cycling is proven to get increasingly alive¹⁰,¹¹. Hence, it is an attractive strategy to achieve an increased cardiorespiratory fitness, reduced body fat and a potential minimization of the risk of cardiovascular diseases.

The purpose of this study is to assess body composition and serum lipid profile of overweight women undergoing 12 weeks of low-calorie diet with or without indoor cycling training.

Methods

After completion of sample size calculation, we randomized (by generating random computer numbers) 40 healthy
women, according to the American College of Sports Medicine (ACSM)\textsuperscript{12}, who volunteered to start an indoor cycling program. These were divided into four groups: indoor cycling group (IC), indoor cycling associated with low-calorie diet (CD), diet group (D), and control group (C). Each group consisted of 10 women.

All volunteers were informed orally and in writing on the procedures of this study, and agreed to sign a post-informed consent. This study complied with the standards for research involving human beings\textsuperscript{13}. Data collection was divided into 4 stages:

**Step 1: assessment of body composition**

It was measured through anthropometric methods and according to the protocol cited by Lohman et al\textsuperscript{14}. The following variables were measured: body mass (BM), height, body mass index (BMI), body fat percentage (BF\% ) and lean body mass (LBM).

Body mass (kg) and height (m) were taken with a scale (Filizola\textsuperscript{15}, Brazil) with 100 g precision and scale of 0 to 150 kg, which a stadiometer attached.

The body mass index (BMI) calculated by dividing these two measures (kg/m\textsuperscript{2}) was used to classify obesity according to the cutoffs recommended by Ardern et al\textsuperscript{15}.

The fat percentage was recorded according to Jackson and Pollock’s seven skinfolds protocol\textsuperscript{16}, using a skinfold caliper (Lange\textsuperscript{17}).

**Step 2: diagnostic evaluation**

It was performed by the laboratory Sérgio Franco Medicina Diagnóstica and the following variables were measured through blood collection: triglycerides (TG), low-density lipoprotein (LDL), very low-density lipoprotein (VLDL), high-density lipoprotein (HDL), and total cholesterol (TC). For the measurements of HDL, CT and TG, we used the enzymatic colorimetric method. VLDL and LDL were calculated by the Friedewald equation, and all values are expressed in mg/dl.

Individuals from all of the four groups (C, CI, GD & D) carried out the procedures for the 1\textsuperscript{st} and 2\textsuperscript{nd} stages, which occurred in the same week.

**Step 3: Intervention**

*Indoor cycling* - It was performed by the groups CI and CD through an interval training model with short periods of active recovery that would allow recovering the exercise performed. The classes were three times a week. Each session consisted of approximately 45 minutes in a transitional period of 12 weeks. Groups CI and CD took the classes at different times, but following the same protocol.

The intensity was controlled by heart rate, musical bpm to determining the rhythm and perceived exertion (overload).

Heart rate monitoring was done with the help of four employees through a Polar\textsuperscript{18} frequency meter (Finland), model F1.

The training was conducted at the target zone 55 $\pm$ 5% to 85 $\pm$ 5% HR$_{\text{max}}$ using the Inbar\textsuperscript{19} equation:

$$HR_{\text{max}} = 205.8 - 0.685 \times \text{age}$$

To control the rhythm, we used the musical BPM music (number of beats per minute of music). Music plays an important role in encouraging the participants, but it is also a teaching tool to determine the rhythm of the techniques selected, since there is a direct correlation of bpm and rpm\textsuperscript{11}.

Overload control was performed using Borg’s Perceived Exertion Scale through a table attached close to the bikes. The exertion degree was represented by numbers.

*Low-calorie diet* - The CD and D groups were assisted by the same dietician using a food recall. During the study period, the individuals participated in biweekly meetings. In all cases, besides the nutritional assessment, the targets effectively achieved were recorded. Then, the participants had the opportunity to express the difficulties they felt in following the instructions given in the previous medical appointment. They were directed on the possible ways to overcome such difficulties.

Energy consumption was approximately 1,200 kcal/day. These were divided into about eight meals (with an interval of at least two hours and a maximum of four hours). The individuals were instructed not to replace the main meals for snacks, always respect the times and quantities and have at least two liters of water per day. The period for this restriction was 12 weeks.

Each individual received, in addition to the diet prescription with a list of possible replacement items (always respecting the quantities), notes and information on the eating routine.

**Step 4: reassessment**

After 12 weeks of intervention, the experimental groups performed the same procedures and protocols described in steps 1 and 2.

For data analysis we used descriptive statistics\textsuperscript{16} through measures of location (mean) and dispersion (standard deviation). The homogeneity of the samples was measured through kurtosis, and normality through the Kolmogorov-Smirnov test. Inferential statistics techniques were used to compare the means through Student’s t test and Anova (analysis of variance) in inter and intra-group analysis. Subsequently, we applied Tukey’s Post Hoc Analysis to identify and determine the group with significant result. We used a significance level of 95\% (p < 0.05).

**Results**

The average age of the 40 women was 23.90 $\pm$ 3.10, and there was no difference between the groups. All groups presented a normal and homogeneous distribution for all variables analyzed. We found a high body fat percentage (BF\%) for the average age of the groups and a BMI between 25.0 kg/m\textsuperscript{2} and 30.0 kg/m\textsuperscript{2} which enabled us to classify them as overweight (Table 1).

Table 2 revealed normal and homogeneous distribution of lipid profile variables over the four groups, as well as determination of normality. The groups above presented normal and homogeneous distribution for all variables.

TG - triglycerides; CT - cholesterol, LDL - low-density lipoprotein, HDL - high-density lipoprotein, VLDL - very low-density lipoprotein; KS - Kolmogorov-Smirnov.

analyzed. Comparing the average results produced with the reference values of plasma lipids recommended by the 3rd Brazilian Guidelines for the Prevention of Atherosclerosis of the Department of Atherosclerosis of Brazilian Society of Cardiology, the four groups were found to be within desirable limits.

Table 3 shows the results of the mean anthropometric variables of the four groups before and after 12 weeks of intervention. Groups CI, CD and D presented a significant reduction in BM, BMI and body fat percentage. There was a significant reduction in LBM only in group D. The inter-group analysis found no difference in BF% between groups C and CD.

The study found that the mean serum lipids of groups CI, CD and D before and after 12 weeks of intervention revealed positive changes in TG, LDL and VLDL. As to the TC, reductions were observed only in groups CD and D. By analyzing the HDL, groups CI and CD presented significant increases. Groups CI, CD and D achieved an optimal classification for the variables TG, TC, HDL and VLDL. Even though LDL was significantly reduced, it remained in the desirable category (Table 4).

The intergroup analysis revealed positive differences in HDL between groups C and CD (p = 0.02), CI and D (p = 0.05) and CD and D (p = 0.016); and VLDL between groups C and CI (p = 0.03) and C and CD (p = 0.00).

Discussion

By analyzing the results presented by the groups CI, CD and D, after 12 weeks of intervention, we find reduced average values for the variables BM, BF% and BMI. Scientific evidence suggests that the combination of dietary changes associated with exercising is the most effective behavior for weight loss.

Groups CI and CD had no changes in LBM, which is something that did not occur with group D, which had a reduction of about 2 kg. Several studies claim that the diet alone can lead to a reduction in BM and that the inclusion of an exercise program can maintain such reduction. Based on these findings, we can say that indoor cycling has contributed to the maintenance of LBM.

Based on the positive changes on the anthropometric variables presented by the groups CI and CD, we can say that the reduction in BM by both is related to the reduction in the body fat percentage, considering that the LBM was maintained.

Monteiro et al observed the effect of a mixed nutritional intervention program and exercising on body composition of obese women. The sample was divided into two groups. One made only the diet and the other made the diet associated with exercise. BM reduction was higher for the group that exercised while on a diet (-2.3 kg for the diet group and -5.3 kg for the exercise group)
It is known that obesity is related to impairments in lipid metabolism. A research work by Coelho et al.\(^{27}\) in 153 medicine students (18 to 31 years old) revealed high levels of CT and TG only in obese individuals. The mechanisms linking high levels of body fat with dyslipidemia are not fully understood. However, it is suggested that the exacerbated increase in the lipolysis rate results in high concentrations of nonesterified fatty acids, contributing to increased hepatic synthesis of VLDL. Besides, it inhibits glucose uptake stimulated by insulin, in a dose-dependent way, resulting in insulin resistance.\(^{19}\)

Although the individuals of this study were overweight and had a desirable lipid profile, we can observe a reduction in the anthropometric variables and consequently in the serum lipid profile.

Groups CI and CD, which conducted indoor cycling training, presented a decrease in the variable HDL. A meta-analysis\(^{29}\) of 31 studies, including 28 randomized controlled trials with more than 12 weeks of training with aerobic exercising, from moderate to high intensity, some of which were combined with dietary intervention, showed a great variability of lipid profile responses, in which the increase in HDL was the most striking finding (47% of studies) and, less frequently, the reduction of TG, CT and LDL.

The sedentary lifestyle is a behavior clearly identified with increased levels of body fat and dyslipidemia. It is known that obesity is related to impairments in lipid metabolism.\(^{28}\) A research work by Coelho et al.\(^{27}\) in 153 medicine students (18 to 31 years old) revealed high levels of CT and TG only in obese individuals.

The mechanisms linking high levels of body fat with dyslipidemia are not fully understood. However, it is suggested that the exacerbated increase in the lipolysis rate results in high concentrations of nonesterified fatty acids, contributing to increased hepatic synthesis of VLDL. Besides, it inhibits glucose uptake stimulated by insulin, in a dose-dependent way, resulting in insulin resistance.\(^{19}\)

Although the individuals of this study were overweight and had a desirable lipid profile, we can observe a reduction in the anthropometric variables and consequently in the serum lipid profile.

Conclusion

In view of the above, indoor cycling and diet proved to be excellent strategies to fight overweight and improve serum lipids. Thus, the study reports the importance of adopting a healthy lifestyle through dietary intervention and inclusion of exercising habits. The greater the diversity of beneficial exercises for proper lipid control and BM reduction, each
individual will have more opportunities of choosing their preferred exercise and engaging in exercise programs.

**Recommendations**

It is suggested that future studies investigate other populations, such as male overweight individuals, for example. It is also recommended to increase the sample in order to provide greater consistency to the widespread application of the results in this specific population; and perform the following measurements: waist circumference and waist-hip ratio, since these are directly linked with risk of dyslipidemia.
