INTRODUCTION

The cryptorchidism is the most common congenital malformation of the genitourinary tract. The intra-abdominal testicle is subject to complications such as cancer, ischemia and infertility. The most common malignant transformation of the undescended testicle is the seminoma. Here is presented a case of adult massive pelvic mass corresponding to seminoma developed in intra-abdominal tests.

CASE REPORT

MC’S, man, 32, with a history of progressive and painless increased abdominal size four weeks ago, no other complaints. He had also several congenital malformations including: pectus excavatum, congenital dislocation of the hip and clubfoot (operated in childhood). Physical examination revealed ascites, bilateral pleural effusion and a hardened mass located in flank and the right iliac fossa of about 20 cm. Was detected the absence of the right testicle in scrotum. No abnormal laboratory tests were present. Computed tomography and magnetic resonance imaging of the abdomen and pelvis showed ascites and heterogeneous pelvic mass (Figure 1). The cytological study of ascites and pleural effusion showed no neoplastic cells.

FIGURE 1 - MRI of the pelvis with heterogeneous mass with well vascularized with areas of degeneration/necrosis (arrows) and superior displacement of bowel loops

Laparotomy was performed which identified a large solid mass in the right iliac fossa partially adhered to the right inguinal canal, and dry easily. The surgical specimen measured 25x19x12 cm and weighed 2350 g (Figure 2). Histopathological examination revealed seminoma of undescended testicle with extensive area of coagulation necrosis and angiolymphatic neoplastic embolization.

FIGURE 2 - Tumor mass with smooth outer surface, opaque, sometimes lobed, with brown bleeding areas in A. When cut, in B, whitish, firm and elastic tumor, permeated by areas of bleeding and yellowish and softened areas.

The patient was discharged on the sixth day after surgery. The left testicle was evaluated and was normal. The staging was completed and once considered the patient in stage III (ascites), was subjected to four cycles of chemotherapy with bleomycin, etoposide and cisplatin, keeping normalization of markers and improvement of ascites. He is currently with eight years of evolution, and in that period maintained regular outpatient follow-up showing no measurable disease to blood tests and imaging.
**INTRODUCTION**

Hepatocellular adenoma (HA) is a rare benign neoplasm of the liver. It is strongly associated with oral contraceptive use by women in childbearing age, by men receiving anabolic steroids and metabolic diseases. HA incidence has raised over the years from 5 per 1 million in 1964 to 4 per 100,000, for unknown reasons.

HA is important because of its risk of complications such as life threatening rupture of the tumor and malignant transformation. Surgical treatment in ruptured HA has a high mortality rate but it is still the standard procedure in those cases. Emergency liver resection in ruptured HA has a mortality rate from 5-10%, but in elective resections the mortality rate is under 1%.

Different procedures have been suggested to decrease mortality rates and spare liver parenchyma, such as arterial embolization of ruptured adenomas, although it is not an available procedure in most centers.

**CASE REPORT**

A 44-year-old woman admitted in the emergency department of another hospital with complaints of sudden upper quadrant abdominal pain. She had been using oral contraceptives for 31 years. She presented with acute mild abdominal pain in epigastrium as well as hypochondrium pain followed by light dyspnea and dizziness. She was treated with analgesics and ordered an abdominal ultrasound made only three days after the pain. The ultrasound showed a solid liver mass in the right hepatic lobe measuring 150x100x100 mm. She was discharged without additional treatment.

After almost five months after the occurrence, she was referred to our surgical department for diagnostic investigation after another episode of abdominal pain just like the last time, followed by tachycardia and cold sweating. Physical examination revealed mild anemia and a diffuse abdominal pain, without peritonitis or palpable masses.

Lab exams showed 8.61g/dl haemoglobin, white blood count 8.980/mm³ and 214.00 platelets. Liver transaminases level were altered: ALT 306 IU/l, AST 154 IU/l, alkaline phosphatase 142 IU/l and gamma-glutamyl transferase 229 IU/l. Alfa-fetoprotein and clotting functions were normal.

Abdominal CT and MRI showed an enlarged liver, with a contrast enhanced liver mass involving segments VI and VII. The liver mass measured 118x70mm and the right hepatic artery. The procedure continued with two bags of packed red blood cells and intensive electrolytes control. Patient was sent to the operation room and had an open laparotomy with strong adhesions to the right diaphragm. It was decided to make an anterior approach with inflow control due to life threatening rupture of the tumor and malignant transformation. Surgical treatment in ruptured HA has a high mortality rate but it is still the standard procedure in those cases. Emergency liver resection in ruptured HA has a mortality rate from 5-10%, but in elective resections the mortality rate is under 1%.

Different procedures have been suggested to decrease mortality rates and spare liver parenchyma, such as arterial embolization of ruptured adenomas, although it is not an available procedure in most centers.
