Abstract:

Glomus tumor is a painful tumor derived from the glomus terminal which regulates blood circulation and body temperature. Despite its rarity, paroxysmal attacks of pain associated with skin lesions can occur. It most commonly affects the extremities but may also involve the head and neck. Informed consent was obtained from the patient and written permission for publication. The histopathological examination of the skin lesion revealed metastatic adenocarcinoma with signet-ring cells, leading to a final diagnosis of Stage IV gastric cancer. Metastases cutaneous of visceral cancer are relatively rare, with an incidence of 0.7-10%. The most common primary sites are gastrointestinal tumors, followed by adenocarcinoma of the breast, lung, and ovary. The presence of metastases can indicate a more advanced stage of the underlying disease and signify a worse prognosis. Curative treatment consists of surgical excision of the primary tumor and metastases, as well as chemotherapy and immunotherapy.
