Abstract: BACKGROUND: Lichen planus is considered to be the most common dermatological disease involving the oral mucosa. OBJECTIVE: To investigate the profile, clinical features, and the presence of dysplasia and candidiasis in patients with oral lichen planus. METHODS: A total of 21 patients were selected from 258 patients at risk for oral cancer development. RESULTS: Most of the patients were white (76.2%), female (66.6%), with mean age of 58.8 years. Eight were smokers and seven were alcohol consumers. The buccal mucosa was the most affected site, followed by the tongue and the gingiva. The reticular pattern was the most common appearance. Histopathology depicted dysplasia in nine cases and cytopathology was positive for Candida in eight cases in the first appointment. CONCLUSION: Our data are similar to the literature. Cytopathology was important for the diagnosis of candidiasis. Although the presence of dysplasia was verified, further studies are necessary to clarify the importance of this finding.

Keywords: Candidiasis, chronic mucocutaneous; Epidemiology; Lichen planus, oral

INTRODUCTION

Lichen planus is a mucocutaneous disease characterized by nonspecific inflammation. It leads to the severe destruction of the epithelial basal layer. The prevalence of oral lichen planus (OLP) ranges from 0.5% to 2.2% of the population and it is considered the most common skin disease involving the oral mucosa. The typical age of onset ranges from 30-60 years, and it is more common in women. OLP usually presents bilaterally on the oral mucosa and has various patterns, with reticular, erythematous (erosive), plaque and ulcerative being the most common. These patterns may coexist in the same region or may alternate in time. The most commonly affected sites are the buccal mucosa, the tongue and the gingiva. Involvement of the palate and lips is rare, and even rarer is the involvement of the oral floor. Burning symptoms, itching and pain are particularly seen in the ulcerative and erythematous variants.

The diagnosis should be based on clinical and histopathological examination. In classical lesions, only clinical diagnosis is possible. In the absence of typical manifestations of the reticular pattern, other patterns may be difficult to diagnose. In these cases, a biopsy is indicated.

It is clear that OLP is an incurable disease. However, the disease has periods of exacerbation and remission. During exacerbation, both the erythematous/ulcerated areas and the pain increase. These periods may be related to stress, anxiety or mechanical trauma. Several protocols for monitoring the disease have been described. They are usually based on the clinical aspect, the number of areas involved and the severity of symptoms.

Several studies report the malignant potential of OLP. However, this topic is still quite controversial. The frequency of malignant transformation varies between 0 and 3.5%, and erythematous and erosive lesions show the highest index. The association be-
The aim of this study is to investigate the clinical features and the presence of dysplasia and candidiasis in OLP lesions, as well as the profile of patients seen at the Ambulatorio de Diagnostico Oral of the Antonio Pedro University Hospital / UFF.

MATERIALS AND METHODS

This is a retrospective study conducted between 2005-2011 with 258 patients considered at risk for developing oral cancer. The mean follow-up interval for each patient was around 4 months. Of the total number of patients, 21 were diagnosed with OLP and were included in the final sample. All the data from each patient were registered in their respective medical records. These contained information on the clinical history and physical examination, which were necessary to characterize the profile of the patients. Details were described with emphasis on the lesions, using images captured during the intra-oral examination.

The clinical and histopathological diagnostic criteria for OLP were based on the studies by Van der Waal and Van der Meij. These studies report that most cases occurred in the seventh decade of life. Between smoking and OLP is still not clear, nor is the relevance of infection by Candida spp in OLP lesions.

RESULTS

Fourteen patients (66.66%) were female. The mean age was 58.8 years for women and 55.8 for men. Most subjects were white (n=16; 76.2%). Seven (30%) participants were smokers and eight (38.1%) were alcohol consumers. Significantly more women than men reported never having smoked (47.6% and 19%) or consumed alcohol (42.8% and 19%).

Most subjects had multiple oral lesions. The buccal mucosa was the most commonly affected site (n=17; 81%), followed by the tongue and the gingiva (n=7; 33.4% each). (Table 1)

The reticular pattern alone was observed in eleven patients. The rest of patients showed reticular pattern associated with other patterns. The plaque pattern and the erosive pattern were the second (seven patients) and the third most commonly found patterns, respectively. In three patients, the latter was associated with other patterns. (Table 1)

All patients had lesions clinically compatible with OLP. Eighteen patients underwent biopsy. Three patients refused to undergo biopsy. In all cases where a biopsy was performed diagnostic histopathological features of OLP were found. Nine cases showed epithelial dysplasia: eight cases had mild epithelial dysplasia and one case had moderate epithelial dysplasia. (Figure 1)

Cytopathological examination was performed in all lesions with the aid of an endocervical brush. We obtained three smears from each lesion. These were stained by Papanicolaou’s (PAP) method and with periodic acid-Schiff (PAS). For the slides stained by Papanicolaou’s method, the analysis of the cellular changes associated with candidiasis was performed according to the following criteria (Bibbo & WILBUR, 2008):

presence of grouped and overlapping keratinized cells associated with polymorphonuclear leukocytes (PMN) and cellular alteration of inflammatory nature - presence of a perinuclear halo, as well as Candida spp hyphae and/or pseudohyphae (more easily identified in PAS-stained slides).

Histopathology was used for the definitive diagnosis of OLP and considered as the gold standard. All samples were fixed in 10% formalin and stained with hematoxylin and eosin, and PAS.

DISCUSSION

We found a predominance of OLP among female patients. This finding is in line with the literature, which reports a ratio of 2:1.3,5,7,9

Most cases of OLP occur between the fourth and sixth decades of life. Most study has reported that most cases occurred in the seventh decade of life. However, in this study we only found three cases older than this age group.
The clinical presentation of OLP can be variable and may initially go unnoticed. We found that the bilateral buccal mucosa was the most commonly affected site, followed by the tongue and the gingiva. According to the literature, the reticular pattern is the most frequent pattern, followed by the erosive pattern. However, in this study we found that the reticular pattern was the most common pattern, followed by the plaque pattern. The tongue and the gingiva are common sites of involvement of plaque-like OLP, which perhaps explains the occurrence of this pattern as being the second most commonly found in this study. Although many patients are asymptomatic and do not require therapy, some patients - especially those with erosive and atrophic lesions - pose a challenge to treatment. Systemic corticosteroids should be reserved for acute exacerbations and disseminated lesions, reducing inflammation and pain. During treatment of OLP the manifestation of candidiasis is a common consequence of the use of topical corticosteroids. Chainani-Wu et al. reported that candidiasis was infrequent and associated with topical corticosteroids. Inflammation and infection by Candida spp. may cause changes in the epithelium that may be interpreted as dysplasia. In our study, cytopathology revealed fungal infection in eight cases in the first appointment and in twelve cases during follow-up.

In general, Candida spp. may be found as a commensal organism in the oral cavity of the population. The determinant of the type of relationship that will exist between Candida spp. and its host is the way it interacts with the colonized epithelial surface. There is clearly a delicate balance between the effects of the potentially harmful virulence factors produced by Candida spp. and the nature of the host’s immune response.

R: reticular; E: erosive; P: plaque

An imbalance in this mechanism causes the relationship between fungus and host to change from commensal to pathogenic. The Candida spp. colonizes the mouth in the form of yeasts. However, when the epithelium undergoes some kind of change with trauma, hormonal factors, immunosuppression, etc., the fungus may invade the underlying connective tissue. It then takes the form of hyphae and produces hydrolytic enzymes that are identified by the body as pathogenic factors, which triggers an immune response. Thus for the diagnosis of candidiasis it is necessary to identify the hyphae and/or pseudohyphae which are associated with the inflammatory criteria.

Spolidorio et al. (2003) studied the occurrence of Candida spp. in oral mucosa lesions and found the presence of this fungus in nine lesions from a total of 54 patients with OLP. They reported that the most accepted interpretation for the presence of candidiasis in these lesions is that it is a secondary colonizer of a previously altered mucosa.

Kragelund et al. (2012) reported the presence of Candida spp. in 16 of 30 patients with OLP. Five patients showed no signs or symptoms of the presence of this fungus. We found the cytopathological examination to be an important part of the treatment protocol of patients with OLP, and it may aid in the diagnosis and in therapeutic decision-making. Patients with candidiasis may or may not show signs and symptoms of the disease. Candidiasis may also exacerbate the symptoms of OLP. Cytopathology is a tool for the identification or confirmation of candidiasis and its treatment may alleviate the existing symptoms. As previously mentioned, candidiasis may alter the epithelium and the inflammatory response. The performance of the cytopathological examination - prior to biopsy - may aid in the diagnosis and treatment of candidiasis, providing the pathologist with better material for analysis and diagnosis.

most patients with oral cancer. Some studies emphasize the need for these patients to avoid or discontinue smoking and alcohol consumption in order to reduce the risk of malignant transformation. González-García et al. reported that there is no significant association between OLP and tobacco and alcohol consumption. Murti et al. found no significant risk when comparing the relative risk of transformation of OLP into cancer in a smoker. In their study, the authors found epithelial atrophy in 74% of the 94 biopsies performed and suggested that this atrophy would result in a greater vulnerability against carcinogens. It was not the aim of this study to evaluate the influence of alcohol and tobacco consumption on OLP. However, given the data in the literature and the possibility of malignant transformation of OLP cited by some studies, we suggest that patients with these habits are more cautiously monitored and encouraged to discontinue smoking and alcohol consumption.

The clinical and histopathological definition of OLP was made by the WHO in 1978. Histopathology has been used in its diagnosis ever since. Van Der Mei and Van Der Waal compared clinical and histopathological criteria of OLP and concluded that there appeared to be a lack of clinicopathological correlation in the diagnosis. Fernandez-Gonzalez et al. considered the clinical and histopathological criteria established by the WHO and modified by Van Der Mei and Van Der Waal, i.e., presence of bilateral lesions; reticular lesions; all atrophic, erosive, bullous or plaque lesions associated with the reticular pattern; presence of a subepithelial inflammatory infiltrate in band-like pattern, degeneration of the basal layer, and absence of epithelial dysplasia. If all clinical and histopathological criteria were present, the lesion would be considered to be lichen planus, in case some criterion was not present, it would be regarded as being compatible with lichen planus. In this study, according to this classification, we found a definite diagnostic correlation in 48% of patients. The rest of patients was classified as having lesions compatible with lichen planus.

All patients are currently being followed up. Some studies suggest that patients with OLP have a higher risk of developing squamous cell carcinoma than the general population. In 1978, Krutchkoff et al. warned about the lack of data in the literature supporting the number of reported cases of malignant transformation of OLP. Van der Meiji et al., agreed with this statement and claimed that two thirds of the cases of OLP with malignant transformation were not sufficiently documented to be considered. These authors believe that most cases of malignant transformation are the result of a mistake in diagnosis. In fact, the diagnosis of OLP demand experience and knowledge from clinicians and pathologists.

Van der Meiji et al. concluded that lichenoid lesions carry a much higher risk of malignant transformation than OLP lesions, and that the monitoring of lichenoid lesions with atrophic/erosive/ulcerative areas is of special importance. Murti et al. found 4% of epithelial dysplasia in 94 biopsies. Only three cases developed cancer from OLP and two of them were smokers. In this study, nine of the 18 patients who underwent biopsy were found to have mild or moderate epithelial dysplasia. Thus, we believe that OLP really is a lesion with malignant potential and that, at some point, some dysplastic change will be present.

CONCLUSIONS

The profile of the patients who constituted our study sample showed no differences from the literature data. The most frequently observed pattern was the reticular pattern. However, the second most common pattern was the plaque pattern, which may explain the finding of the tongue as the second most common site of occurrence of OLP. Candidiasis was present in a little over a third of cases in the first appointment and in more than half of cases in the follow-up visits. Cytopathology proved to be an important tool for diagnosis. Dysplasia was identified in more than half of cases. Nevertheless, a longitudinal study should be conducted in order to investigate the meaning of this finding. Lesions clinically compatible with OLP should undergo biopsy for definitive diagnosis and should be followed up for life. In case changes in the appearance of these lesions are found during follow-ups, further biopsies should be carried out, because their malignant potential is not yet clear.
