Association between visual impairment and depression in the elderly: a systematic review

Associação entre deficiência visual e depressão em idosos: uma revisão sistemática

ABSTRACT
A systematic review was conducted to investigate the relationship between visual impairment and depression in the elderly. We searched electronic databases (LILACS, SciELO, MEDLINE, and Cochrane Central Register of Controlled Trials) from inception to August 2014 and researched the described references. The search strategy used the following terms: (visual impairment or blindness) and (elderly) and (depression). Of the 641 electronics, 42 works were selected in full and another 20 were identified as being possibly relevant. Ten studies were included. The studies ranged in sample size from 31 to 21,995 participants. Depression was associated with visual impairment in all studies; however, without standardization of diagnostic tests, we could not conduct a meta-analysis or establish a relationship between visual impairment and depression in the elderly.

Keywords: Visual impairment; Depression; Aging; Blindness; Vision loss

INTRODUCTION
Visual impairment (VI) is becoming a major public health concern with the aging of the population. It is the third most prevalent physical impairment among older adults (11). Visual impairment affects one-third of elderly subjects, with the prevalence of mild or severe VI ranging from 4% to 12% (2,3). Ultimately, untreated eye disorders can contribute to avoidance of social situations, resulting in social isolation or leading to substantial physical decline, which may ultimately require a transition into an assisted living arrangement (4). A number of studies suggest that disability may contribute to depression (5,6); depression is the most common psychiatric disorder and carries a high burden in terms of treatment costs, effect on families and carers, as well as loss of workplace productivity (6). The World Health Organization (WHO) currently ranks it as the third most prevalent moderate to severe disabling condition globally. It may become a chronic disorder with ongoing disability, particularly if inadequately treated, contributing to the global burden of disease (7). Results from a number of population-based (8-12) and hospital-based studies (13,14) indicate that VI is associated with higher rates of depression.

This review aimed to verify whether there is an association between VI and depression in the elderly.

METHODS
The PRISMA guidelines (15) were followed for this review, and the sections below are set out according to these guidelines.

Articles that reported depression, as analyzed by the Geriatric Depression Score (GDS) or another specific scale, in adults aged 65 years and older with VI (visual acuity worse or equal to 20/70 or 0.55 in logMAR) or mild VI (visual acuity worse than 20/40 or 0.3 in logMAR) were included (16). Cross-sectional, cohort studies, or case-control studies were also included. Any setting was permitted (primary care, secondary care, or general population), although the search was limited to articles in English or Portuguese. Review studies, unpublished articles, abstracts, theses, dissertations, and book chapters were not included. Articles regarding dual sensory loss (hearing and VI) were excluded, as were studies about a single ocular disease and those not reporting about VI as the primary objective.

The primary outcomes associated with the aim of this review were depression, most frequently evaluated using GDS (17) or the Center for Epidemiologic Studies-Depression scale (CES-D) (18) and visual acuity. Secondary outcomes analyzed included sociodemographic variables (age, gender, marital status, ethnicity, years of education, living alone or not, social activities), visual function (VF questionnaires), visual field, disability (analyzed by the Community Disability Score (CD-30) or Activities of Daily Living (ADL)), chronic disease, mortality, anxiety [measured using the State-Trait Anxiety Index (STAI-6) or General Health Questionnaire Score (GHQ-28)], physical activity, quality of life [measured using Short-Form Health Surveys (SF)], number of antidepressive medications, previous history of depression, duration of institutionalization if present, and duration of VI.

To gather as many studies as possible on the issue, the strategy for data collection aimed to identify articles that presented the de-
Association between visual impairment and depression in the elderly: a systematic review

Measures of depression

Depression was measured using a number of different tools, the most popular being GDS-15, used in eight studies. GDS-15 is a self-administered questionnaire consisting of 15 items that are related to depression. It was specifically developed for older people and places less emphasis on somatic symptoms than other generic depression scales. It asks respondents to answer “yes” or “no” to 15 questions about how they have felt in the past week. GDS-15 is a screening tool for depression rather than an assessment scale providing a clinical diagnosis of depression; the level of depressive symptomatology is related to the level of depression. In these studies, the cut-off for depression ranged into four or more (21), five or more (22,23), six or more (24,25), and 11 or more (26). Another questionnaire that was used was CES-D, used in two studies (27,28). CES-D records the frequency and severity of depressive symptoms over the preceding week via a 20-item questionnaire. Each item is scored on a scale from 0 (less than 2 days duration) to 3 (5-7 days, both days inclusive), and a score of 16 or more indicates major depression. One of the studies (28) used depression diagnosis based on the International Diseases Code (ICD-10). Because of this heterogeneity, meta-analysis was not possible with this variable.

Measures of visual acuity

Visual acuity was presented as logMAR, decimal, or fraction standards and was measured using the Snellen chart (seven studies), Glasgow acuity chart (one study), ETDRS chart (one study), or subjective vision (one study). One study considered VI a visual acuity less than 20/80 and analyzed visual function with the VF-14 score, which records the degree of deficiency in vision affecting daily activities, and visual acuity to high and low contrast (27). Another study analyzed three groups: one with no VI (visual acuity of 6/6 or better), one with...
Some studies considered visual acuity less than 20/70 (based on ICD-9 and -10) as VI (4, 23, 25); however, only one study measured near and distant visual acuities (4). Two studies considered VI as visual acuity less than 20/40 or visual field defects (22, 23). One study analyzed blindness (visual acuity of 20/400 or worse) (26) and another analyzed visual loss with a subjective questionnaire of self-reported activities that the person can or cannot answer because of his vision (12); it was not possible to perform meta-analysis with this variable because visual acuity was measured using different methods in each article.

### Depression and Visual Impairment

Despite heterogeneity between the groups of visually impaired subjects and the group of depressed subjects, it was not possible to perform statistical analysis.

### Anxiety and Depression

Anxiety was just analyzed in two studies. In one study, it was recorded using STAIt-6 and was associated with VI and depression (21). Another study used GHQ-28 (24) to analyze anxiety, and it was not possible to perform meta-analysis.

* L = low risk of bias; U = uncertain risk of bias; H = high risk of bias.  
* = only for longitudinal studies.
Quality of Life and Depression

Quality of life was analyzed in one study (20) by the SF-36 score and had an association with depression with regard to a low quality-of-life score. SF-36 generates a Mental Component Summary (MCS) and a Physical Component Summary (PCS) score. SF-36 can also be considered a disability measure because the questions are worded to reflect limitation in ability related to health issues.

Limitation in Daily Activities and Depression

A limitation in daily activities and depression was measured using the Nottingham Extended Activities of Daily Living Index (NEADL) in one study (20). In this scale, a low score suggests that the person is dependent in his activities. In another study, ADL was used (21-23).

Physical Activity and Depression

This variable was measured in only one study (21) using the Human Activity Profile (HAP), which records the respondent's highest level of energy expenditure and generates the maximum activity score.

Disability and Depression

Mobility in one study was measured using the Life Space assessment (LS-C-120), a questionnaire that records the frequency of going to different level spaces at home and outside in a month (22). Disability was also analyzed in one study (27) using CDS-30 and in another using the Oregon Administrative Rules (OAR) instrument (28). It was impossible to perform meta-analysis for this factor.

Mortality and Depression

Mortality and depression was analyzed only in one study (28), because of this, it was not possible to perform meta-analysis.

Chronic Diseases and Other Comorbidities in Depression

Two studies reported an association between chronic diseases and depression, measured using CDS; another study just analyzed specific diseases such as diabetes, cardiovascular diseases, and stroke (23,24) using two different methods; therefore, it was not possible to perform statistical analysis.

Ocular Diseases and Depression

One study compared three ocular diseases as the cause of VI (22). Age-related macular degeneration (ARMD) was compared in two other studies to the prevalence of other ocular diseases (ARMD 61.4%, cataract 31.4%, glaucoma 21.4%, diabetic retinopathy 15.7%, and others 5.7%) in visually impaired patients (21,27). Therefore, it was not possible to compare these different data.

Risk of Bias in the Articles

Most articles had L and U (low and uncertain risk) in the major items of the quality scale used. The risk of bias in the studies included is summarized in Table 2.

Discussion

Depression is a major public health concern among the elderly. It causes suffering, family disruption, disability, worsening of the outcome of many medical illnesses, and increased mortality (20). The prevalence of depression among the elderly varies. Almost 3% of the elderly population suffers from major depression; 8%-16% of the elderly have clinically significant depressive symptoms (18).

Rates of VI in the elderly increase with age and are associated with functional loss, mortality as well as psychological distress, sense of loneliness, and depression. Given that depression is treatable and some ocular diseases that cause visual loss are reversible, early identification and treatment of persons most at risk could have an important impact in the well-being of the elderly (20).

The studies included in this review were observational, with half of them being cross-sectional, and these study designs do not show causality. Therefore, it is difficult to confirm a temporal relationship between depression and VI. The limitations of this review were the inadequate definition of outcomes and lack of responses by some authors regarding missing data.

The sociodemographic variables were not associated with depression in most articles. In one study, men were more depressed than women. In another, women had a higher incidence of depression than men. Another study showed that a low level of education is associated with greater symptoms of depression (20).

The outcome depression was analyzed using GDS-15 in six studies (20,21,22,24,25,27,28); nevertheless, the cut-off for depression varied in these studies, limiting the comparison between heterogeneous groups.

Only one study analyzed a previous history of depression or the use of antidepressant medicine, which is, by itself, a risk factor for depression (20).

Depression was related to VI in all studies (prevalence ranged from 8.8% to 45.2%).

Visual acuity was assessed using different methods (Snellen, Glasses, and ETDRS), and only one study (20) evaluated the Visual Function Score (VF-14), and this variable was associated with depression. The same study also assessed high- and low-contrast visual acuity, and both were related to more depression. Only one article assessed near and far visual acuity (28) and found that only far visual acuity was associated with depression.

Most articles used the best-corrected visual acuity; nevertheless, just one article (20) related that refraction was done when visual acuity was low, considering that refractive errors are reversible (21).

The criteria to determine VI varied between the studies. One study used ICD-9 (20), while another used ICD-10 (24). Most articles did not establish standard criteria to diagnose VI. Consequently, there was a high heterogeneity between the VI groups, ranging between worse than 20/40 (24) and worse than 20/70 (21).

The relationship between severity of VI and depression was just reported by two studies (20,21). One study found that the severity of visual loss does not matter and that VI was a risk factor for depression only in participants without a previous history of depression, and this study found that a 2-year history of depression is the most important risk indicator of depression (20). The other study found that there is a positive association of more severe visual loss with depression (25).

One study used a questionnaire with subjective questions about the vision of the participant and what the participant was and was not able to do because of the visual loss. This type of questionnaire could be a risk because there is no objective method to measure the real visual acuity in these cases (27).

Only two authors evaluated baseline and follow-up visual acuities, and they found that the follow-up visual loss was associated with depression (20,21). The two studies that analyzed the time of visual loss and depression found different results (20,21).

Anxiety was analyzed by two authors, and one found a relationship between anxiety and depression and VI; however, the other did not described such an association (21,24).

Other variables (quality of life, limitation of diary activities, physical activities, and disability) that were previously considered as very important in the association between VI and depression were correlated with depression; nevertheless, they were analyzed in only few studies (21). When advanced age is coupled with low vision, a person's level of activity is narrowed further than with either age or VI alone. Furthermore, although older people can normally adjust well to environmental challenges, when the demands on their body are increased, such as when vision is disrupted, physical limitations may become problematic and affect quality of life (21,27).

The limitation of daily activities was analyzed in two studies, measured using different methods, and it was associated with depression in both (21,27).
In one study⁴¹, the author reported that a high limitation in daily activities is associated with an eight times greater VI and 12 times more depressed people.

One study⁴⁰ reported that the time of institutionalization, when it occurs, is not related with depression. In addition, one study related that living alone is not associated with an increase in depression rates⁴¹. Disability is already well known in the literature as an important risk factor for VI and depression⁴⁰, and it is a major public health issue for the elderly. Age is associated with decreased physical competence and increased prevalence of chronic illness⁴¹. VI is an important, but not life threatening, chronic illness and cause of disability⁴¹ and has been associated with depression in studies⁴²,⁴³,⁴⁴. Different indices were used to assess disability. Low functional ability was associated with depression in one study, as measured using the Barthel index⁴⁵.

Mortality and chronic diseases were described in one and two studies, respectively⁴⁶,⁴⁷, both associated this factor with depression, and these factors are also described in the literature as being important to depression and VI⁴⁸,⁴⁹,⁵⁰. VI causes impaired psychosocial functioning with impaired ADL, loss of independence, reduced social interaction, and depression, and it is known to be related to mortality. In addition, patients may be exposed to shared risk factors for mortality and VI, such as aging, diabetes, vascular pathology, high blood pressure, or smoking⁵¹.

Chronic diseases were assessed by the CDC score in one study and were associated with depression and VI; another study reported that stroke and cardiovascular diseases are related to depression⁵²,⁵³, and there is a strong association in the literature with these risk factors⁵⁴,⁵⁵.

The causes of VI were described in one study⁵⁶, which demonstrated that diseases that cause central visual loss are more associated with depression than those that present with peripheral visual loss. Another study just reported the prevalence of the diseases⁵⁷ without specifying whether any of them is associated with depression.

The implications with regard to clinical practice is that because there is no established link between standardized VI measurements and depression, physicians would have to rely on knowledge and clinical experience to decide when to investigate and treat a depressed visually impaired patient.

This review shows that new research is necessary to analyze each important variable because most studies did not include the full range of common risk factors for both VI and depression, making it impossible to establish a linear correlation between them. In addition, it is important to use standard criteria to classify depression and VI, such as the GDS scale with a standard cut-off to depression and VI criteria following just IDC or WHO.

CONCLUSIONS

After a literature research, we could not definitely establish an association between VI and depression in the elderly. The reasons include a lack of standardized measures of VI and depression to allow comparability of the studies and the potential bias created by several other variables.
