Applications of vestibular-evoked myogenic potentials: a systematic literature review

Revisão sistemática de literatura dos potenciais evocados miogênicos vestibulares

Tatiana Rocha Silva¹, Marco Aurélio Rocha Santos², Luciana Macedo de Resende³, Ludimila Labanca⁴, Júlia Fonseca de Morais Caporali⁵, Marjore Rhaissa de Sousa⁶, Denise Utsch Gonçalves⁷

ABSTRACT

Purpose: To review the scientific literature on the main techniques used to generate vestibular-evoked myogenic potential (VEMP) and its clinical applications. Research strategy: A search for articles describing VEMP recording methods and applications was conducted in the PubMed, Web of Science, MEDLINE, Scopus, LILACS and SciELO databases. The search was limited to articles published in English, Portuguese, and Spanish between January 2012 and May 2018. Selection criteria: Articles addressing the technical aspects for performing ocular, cervical or soleus VEMP with auditory or galvanic stimulation and articles on the clinical applications of VEMP were included in this review, whereas articles repeated in the databases, literature reviews, case reports, letters, and editorials were excluded. Results: The search strategy resulted in the selection of 28 articles. The studies evidenced three methods of VEMP recording: responses from the cervical, ocular and soleus muscle. Clinical applications of VEMP included Meniere’s disease, vestibular neuritis, superior semicircular canal dehiscence syndrome, Parkinson’s disease, central ischemic lesions, and motor myopathies. Conclusion: Regardless of the recording technique, VEMP has proved to be useful as a complementary tool for the diagnosis of peripheral and central vestibular diseases.

Keywords: Vestibular Nuclei; Vestibular-evoked Myogenic Potential; Postural balance; Vestibular function tests; Vestibular nerve

RESUMO

Objetivos: Revisar a literatura científica sobre as principais técnicas usadas para gerar o potencial evocado miogênico vestibular (VEMP) e suas aplicações clínicas. Estratégia de pesquisa: Os artigos que descrevem os métodos de registro e as aplicações do VEMP foram localizados nas bases de dados PubMed, Web of Science, MEDLINE, Scopus, LILACS e SciELO. O levantamento realizado limitou-se aos artigos publicados nos idiomas Inglês, Português e Espanhol, entre janeiro de 2012 e maio de 2018. Critérios de seleção: Artigos sobre os aspectos técnicos para realização do VEMP ocular, cervical ou do músculo só leo, com estimulação auditiva ou galvânica e artigos sobre as aplicações clínicas do VEMP foram incluídos; artigos repetidos nas bases de dados, artigos de revisão de literatura, relato de casos, cartas e editoriais foram excluídos. Resultados: A estratégia de busca resultou na seleção de 28 artigos. Os estudos evidenciaram três métodos de registro do VEMP: cervical, ocular e do músculo só leo. As aplicações clínicas do VEMP incluíram doença de Ménière, neurite vestibular, síndrome da deiscência do canal semicircular superior, doença de Parkinson, lesões centrais isquémicas e mielopatias motoras. Conclusão: Independentemente da técnica de registro, o VEMP mostrou-se útil como ferramenta complementar para o diagnóstico de doenças vestibulares periféricas e centrais.

INTRODUCTION

Vestibular-evoked myogenic potential (VEMP) is an electrophysiological method used to assess integration of the otolith organs and vestibular nerves with the brainstem and the muscular system. Therefore, it is a complementary exam that presents the differential of evaluating the central vestibular function, and it is related to a disynaptic reflex that has been considered to investigate brainstem function\(^1,2\).

The VEMP is generated from the muscle reflex responses resulted of the vestibulo-ocular, the vestibulomasseteric and the vestibulospinal reflexes. These reflexes depend on the functional integrity of the utricular and saccular maculae, the inferior and superior vestibular nerves, the vestibular nuclei, the central vestibular pathways, and the neuromuscular plaques\(^3,4\). Changes in The VEMP are observed if any of the listed structures present injury.

The VEMP has been utilized to study a variety of vestibular diseases. Among peripheral diseases, Meniere’s disease\(^5,6\), vestibular neuritis\(^7\), superior semicircular canal dehiscence\(^8-10\), large vestibular aqueduct syndrome\(^11\) and vestibular schwannoma\(^12,13\) are highlighted, whereas among central vestibular diseases, vestibular migraine\(^14\), Parkinson’s disease\(^15\), central ischemic lesions\(^16-18\), and motor myelopathies\(^19-25\) stand out.

The VEMP can be generated through auditory or galvanic stimulation and evoked responses can be obtained from several muscles such as extraocular, cervical, masseter, intercostal, brachialis, soleus, or gastrocnemius. The basic principle is the action of the muscular response in the postural control, either through vestibulo-ocular, vestibulocollic, or vestibulospinal reflex\(^2,3\). With this approach, VEMP application varies according to the type of stimulation and the electromyographic muscular responses\(^2,3,5\). In its several modalities, this test presents characteristics favorable to its use in clinical practice: objectivity, non-invasiveness, easy execution, low cost, rapidity, and minimal discomfort for the patient. As any other electrophysiological examination, the examiner’s experience is a determining factor for the test reliability\(^22\).

PURPOSE

This study aimed at revising the scientific literature addressing the main techniques used to generate vestibular-evoked myogenic potentials (VEMP) and their clinical applications.

RESEARCH STRATEGY

A systematic review of the literature was conducted, without meta-analysis, based on the following question: What are the different methods used to generate VEMP and their clinical applications? A search was conducted in the PubMed, Web of Science, MEDLINE, Scopus, LILACS, and SciELO electronic databases for articles published between January 2012 and May 2018. The following descriptors were used in the search: *Vestibular-evoked myogenic potential, auditory stimulation, electric stimulation, postural balance*, and *vestibular nuclei*.

Keywords were selected based on consultation with the Health Sciences Descriptors (DeCS) and Medical Subject Headings (MeSH), and were combined using the Boolean operator AND. The following combinations were used: *Vestibular-evoked myogenic potential* AND *auditory stimulation*; *Vestibular-evoked myogenic potential* AND *electric stimulation*; *Vestibular-evoked myogenic potential* AND *postural balance*; *Vestibular-evoked myogenic potential* AND *vestibular nuclei*.

Through these search strategies, 396 publications were found (205 in PubMed, 96 in Web of Science, 35 in MEDLINE, 52 in Scopus, and eight in SciELO). No publications were found on the LILACS database. First, the article titles were analyzed, and those associated with the theme proposed for the review were selected. Titles should make reference to VEMP. A second selection was conducted by analyzing the abstracts, which should include the clinical application of VEMP.

SELECTION CRITERIA

The articles met the following criteria to be included in this revision: 1) be published in Portuguese, English, or Spanish between January 2012 and May 2018; 2) titles should contain the word VEMP and a clinical application should be described in the title or abstract.

Articles that did not address VEMP and their clinical application in the title or abstract, did not mention the characteristics of the VEMP used, and did not describe the results of the evaluation were excluded. Articles repeated in the databases, literature reviews, case reports, letters, and editorials were also excluded from the review.

After analysis, 28 articles that met the inclusion criteria were selected for review. The article selection process was based on the recommendations of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses: the PRISMA Statement\(^26\) (Figure 1).

![Figure 1. Summary of the study selection criteria](image-url)
DATA ANALYSIS

Initially, the studies were analyzed through the reading of their titles and abstracts. Subsequently, the studies included in the review were read in full. The recommendations included in the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE statement) were followed to analyze the selected studies. The following data were extracted from the articles after analysis: authors, year of publication, country where the research was conducted, VEMP recording method, method characterization, recording parameters, sample size, clinical application, and results.

A descriptive analysis of the results was performed and, due to the heterogeneity of the data, it was not possible to perform a meta-analysis.

RESULTS

The Chart 1 presents a summary of the 28 studies included in this review. The variables country of origin and design were described to assist with characterization of the studies included in the review, but are not part of the main outcomes. All articles selected were published in English. The countries with the largest number of publications were the USA (5; 18%) and

**Subtitle:** VEMP = Vestibular-evoked myogenic potential; BPPV = Benign paroxysmal positional vertigo; SSCD = Superior semicircular canal dehiscence
Brazil (3; 11%)\textsuperscript{20,21,29}. Sample size of the studies ranged from eight to 83 individuals with peripheral and central vestibular disorders.

Regarding the design, eight (29%) studies were descriptive\textsuperscript{5,6,16-18,28,30-31}, 19 (68%) were comparative cross-sectional\textsuperscript{7-10,12-15,19-21,29,32-38}, and one (3%) was longitudinal cohort\textsuperscript{39}.

With respect to the diseases, the most commonly investigated clinical applications in patients with vestibular disorders referred to Meniere’s disease\textsuperscript{6-10,29}, superior semicircular canal dehiscence syndrome\textsuperscript{6-10,32}, vestibular schwannoma\textsuperscript{12-13}, and central ischemic lesions\textsuperscript{15-21,36-37}.

Three methods of vestibular-evoked myogenic potential (VEMP) recording were identified in the 28 articles assessed, with the cervical and the ocular as the most commonly used methods (Figure 2).

Concerning the type of applied stimulation, the number (%) of studies using the sound or the electric stimulation were: 19 (68%), auditory - rarefaction tone burst\textsuperscript{6-7,9,12-14,18-21,28-31,33,35-36,38-39}, three (11%), auditory - rarefaction tone burst and click\textsuperscript{5,19,20,34}; two (7%), auditory - click\textsuperscript{10,37}; two (7%), galvanic\textsuperscript{20,34}; one (3.5%), auditory - click and galvanic\textsuperscript{5}; one (3.5%), auditory - rarefaction tone burst and galvanic\textsuperscript{19}. The electric current intensity of galvanic stimulation ranged from 1 to 5 mA\textsuperscript{5,19,20,34}.

Regarding the frequency of auditory stimulation, 500 Hz was predominant - used in 21 (81%) studies\textsuperscript{6-8,10,12-16,18-19,28-29,31-33,35-36,38-39}, followed by 1000 Hz - applied in two (7%) investigations\textsuperscript{17,21}, 600 Hz - used in one (4%) survey\textsuperscript{5}, 250 Hz - utilized in one (4%) study\textsuperscript{30}, and one research used various frequencies\textsuperscript{69}.

Regarding the type of stimulus conduction, 21 (81%) studies used air-conducted sound\textsuperscript{6-8,10,12-16,18-19,28-29,31-33,35-36,38-39}, two (7%) researched applied bone-conducted vibration\textsuperscript{6,30}, and three (12%) surveys utilized both air- and bone-conducted stimulation\textsuperscript{5,12,13}.

All the studies that used VEMP to evaluate Meniere’s disease\textsuperscript{6-29} adopted either cervical or ocular recording. About the type of stimulus, two of these surveys\textsuperscript{6,29} used rarefaction tone burst auditory stimulation at a frequency of 500 Hz and one\textsuperscript{5} applied click auditory stimulation at 600 Hz. Air-conducted sound\textsuperscript{30}, bone-conducted vibration\textsuperscript{60}, and both air- and bone-conducted stimulation\textsuperscript{5} were also observed.

With respect to application to VEMP to superior semicircular canal dehiscence\textsuperscript{6-10,32}, this review verified that three studies\textsuperscript{6-10} used cervical and ocular VEMP recording and one used only cervical recording. Of these studies, one\textsuperscript{9} applied rarefaction tone burst auditory stimulation at variable frequency, one\textsuperscript{10} used click auditory stimulation at 500 Hz, and two\textsuperscript{8,32} utilized both rarefaction tone burst and click auditory stimulation at a frequency of 500 Hz. The air-conducted sound stimulation was the only chosen in all the studies\textsuperscript{6-10,32}.

As for application to vestibular schwannoma\textsuperscript{12,13}, one study\textsuperscript{13} used cervical and ocular VEMP recording and the other\textsuperscript{12} used only cervical recording. One\textsuperscript{12} utilized air-conducted rarefaction tone burst sound stimulation at a frequency of 500 Hz and the other\textsuperscript{13} applied both air-conducted sound and bone-conducted vibration stimulation using rarefaction tone burst and click at 500 Hz.

About VEMP for testing central ischemic lesions\textsuperscript{15-21,36,37}, this review found that one study\textsuperscript{15} used both cervical and ocular VEMP, four\textsuperscript{16,21,36,37} used only cervical VEMP, two\textsuperscript{17,18} only ocular VEMP, one\textsuperscript{20} only soleus VEMP, and one\textsuperscript{19} applied both cervical and soleus VEMP. Of these studies, four\textsuperscript{15-16,18,36} used air-conducted rarefaction tone burst sound stimulation at a frequency of 500 Hz, two\textsuperscript{17,21} applied air-conducted rarefaction tone burst sound stimulation at 1000 Hz, one\textsuperscript{17} utilized air-conducted click sound stimulation at 500 Hz, one\textsuperscript{19} used air-conducted rarefaction tone burst sound stimulation at 500 Hz and galvanic stimulation at an electric current of 2 mA, and one\textsuperscript{20} applied only galvanic stimulation at 2 mA.

The Chart 2 shows a summary of the main characteristics of the VEMP recording methods. Figures 3, 4, and 5 show VEMP recording methods according to the type of stimulation and neural pathway, positioning of the electrodes for muscle response, and electrophysiological waveform generated.

DISCUSSION

The studies about VEMP with auditory stimulation have evidenced this test as an assisting tool for the diagnosis of several types of peripheral vestibular disorders, predominantly Meniere’s disease, motor myelopathies, and superior semicircular canal dehiscence (SSCD), as well as diseases related to central vestibular disorders, such as motor myelopathies and Parkinson’s disease.

In Meniere’s disease, some authors have reported that cervical VEMP changes occur in consequence of the cochleosaccular hydrops, while other authors have understood that the changes depend on the stage of this disease. In early stages of the disease, increased amplitudes are observed in cervical VEMP owing to hypersensitivity of the sacculus, which would be caused by saccular dilatation, whereas in late stages, the amplitudes may be attenuated as a result of atrophy of the sensory epithelium of the saccular membrane. Concomitant changes in cervical and ocular VEMP would be associated with involvement of the sacculus and the utricle, respectively. Therefore, simultaneous alteration of cervical and ocular VEMP occurs more commonly in the advanced stage of Meniere’s disease.

The literature reports that, in SSCD, the cervical and the ocular VEMP recording presents a pattern of response that is different from those observed in other vestibular diseases. Electrophysiological response with auditory stimulation at lower sound intensity (approximately 70 dB nHL) is observed, as well as waveforms with increased amplitude on the compromised side, keeping the normal morphology. This finding has been associated with a change in the bone layer that covers the superior semicircular canal, when that thinner, can cause a decrease in impedance and, consequently, an increased sound transmission to the labyrinth, with greater sensitivity of the sacculus to sound stimulation. VEMP response at low sound stimulation associated with higher wave amplitude that increases according to the level of sound intensity for both the cervical and the ocular potentials, suggest the diagnosis of SSCD and indicate that the central vestibular system is not affected in this syndrome.

Regarding central lesions, studies addressing infectious myelopathies showed that cervical VEMP responses were altered in over half of the individuals with myelopathy. Cervical VEMP enabled to diagnose a spinal disfunction that was subclinical, in addition to assessing the disease evolution.

In Parkinson’s disease, cervical VEMP and ocular VEMP were used to evaluate the postural control. A study that assessed the vestibulocollic reflex in individuals with Parkinson’s disease reported that cervical VEMP responses showed reduced amplitudes. According to the authors, these findings suggest reduction in the reflexes that correlate with the vestibular activity. Another study showed changes in cervical and ocular VEMP responses in patients with Parkinson’s disease and postural instability.

About the type of sound stimulus used to generate VEMP, the tone burst auditory stimulation was identified in several studies and it is justified by the fact that the threshold of saccular excitability is lower for this type of stimulus when compared to click stimulation, and it is more comfortable for the individual. The frequency of 500 Hz is the most common choice because it generates a more homogeneous and constant response.

With respect to the comparison of air-conducted sound and bone-conducted vibration auditory stimulation, some authors believe that the advantage of the latter lies in the possibility of testing individuals with conductive hearing loss. However, bone-conducted stimulation is seldom used, considering that galvanic stimulation, which is independent of the middle ear, offers more robust electrophysiological response.

Studies have observed that VEMP obtained through galvanic stimulation presents the advantage of acting on the postsynaptic membrane, next to the vestibular nuclei and, when associated with other vestibular battery tests, enables distinction between peripheral and central vestibular disorders. As galvanic stimulation reaches the terminal axons of the vestibular nerve in the junction with the vestibular nucleus, when comparing the response to VEMP using auditory stimulation with that of VEMP using galvanic stimulation in the same patient, it is possible to differentiate whether the lesion is vestibular or retrovestibular. For example, in the presence of peripheral vestibular neuropathy, VEMP with auditory stimulation will show altered results, whereas VEMP with galvanic stimulation will present normal result.

VEMP with galvanic stimulation has been proved to be an important tool for the subclinical diagnosis of motor myelopathies and for the definition of the level of spinal cord involvement. For instance, when assessing patients with motor or traumatic myelopathy and submitting them to VEMP with galvanic stimulation with the response recorded in different postural muscles (e.g. cervical, intercostal, and soleus), it is possible to infer about the topodiagnosis of the medullar lesion based on which muscle presented VEMP response. In clinical practice, recording of soleus VEMP triggered by auditory stimulation is difficult to obtain due to lower accumulation of energy, compared with that of the galvanic method, which is much more robust. Thus, for the VEMP of the soleus muscle, the best stimulus is the galvanic one. For ocular and cervical VEMP, the response can be generated with both auditory and galvanic stimuli.

The different methods related to the parameters used to perform VEMP and the presentation of the results limited the comparison among studies. On the other hand, the importance of using different VEMP recording methods to assess otolith function and vestibular pathway is the diversity of vestibular diseases that can be evaluated through VEMP. Therefore, in vestibular electrophysiology research, VEMP has emerged as an outstanding complementary examination to assess vestibular function. The use of VEMP, coupled with other vestibular tests, enables a more comprehensive evaluation and, consequently, a better knowledge about the structures contained in the labyrinth and their neural pathways.

CONCLUSION

In this article, we reviewed the clinical aspects of VEMP, the stimulus modalities and the muscles most used to register the evoked response. Cervical VEMP, ocular VEMP and soleus VEMP are the most used. The auditory stimulus is the most used to generate the cervical and ocular VEMP, while the galvanic (electric) stimulus is the most used to generate the VEMP of the soleus muscle. These tests are very important for the evaluation of peripheral and central vestibular system function.
