ENHANCEMENT OF SODIUM INTESTINAL SECRETION IN RELATION TO ABSORPTION IN MALNOURISHED RATS.

Hyperosmolar challenge

ABSTRACT - Two experimental models were tried in young malnourished rats in order to study effect of an hyperosmolar challenge in the small intestine on the bi-directional fluxes of sodium. Weanling rats were fed with energy restricted diets. In model I 1 mL of NaCl 900 mOsm/kg was introduced in the small intestine of the rats and left from 5 up to 70 min, in order to determine the moment of higher net Na+ secretion, which occurred at 10 min. In model II, the bi-directional fluxes of Na+ and Cl- were studied using NaCl or mannitol 900 mOsm/kg under the effect of mecholil, atropine or 2-4 dinitrophenol, for 10 min. Mecholil decreased the Na+ absorption enhancing the net secretion. Control rats were used as reference. In the restricted diets animals occurred an increase of the net secretion stimulated by NaCl 900 mOsm/kg, and this effect was enhanced by mecholil. It is suggested that in malnutrition there is an impairment in Na+ intestinal absorption.

In spite of the remarkable progress related to hydrosomotic effect on the epithelial apical membrane, the role of osmoreceptors, intracellular modulation of secretory mechanism and paracellular permeability underlying mechanism involving osmoregulation remain unclear(6). New approaches are necessary for a better understanding of such a network of events with emphasis of malnutrition and diarrhea syndromes.

In malnutrition, a condition the enhances liability to contract and maintain diarrhea(15) osmoregulation can be affected and consequently will impair mucosal net transport of solute and solvent. In this situation, morphological and functional changes in small intestine already registered by several investigators in animals or in human beings(11) could be contribute to manager the mucosa capacity under osmolar loads.

The purpose of this study was to test and speculate the osmoregulation capacity of the small intestine in malnourished rats under intraluminal hyperosmolar challenge. Several natural and commercial soups, juices, beverages presented osmolality ranged from 240 to more than 2000 mOsm/kg(5). This study was performed with solutions of 900 mOsm/kg. In model I it was determined the effect of hyperosmolality for 70 minutes in order to obtain the best conditions for this study. In model II a study of an osmotic perturbation was induced by absorbable ion, sodium, or by non-absorbable mannose loads.

Cholinergic, anticholinergic and antimetabolic interferences were studied designed to elucidate specific influences in the bidirecional fluxes of fluid and electrolytes. The malnutrition was attained by feeding the animals with an energy-restricted diet.

MATERIAL AND METHODS

Animals - Young male normal rats (Albinus, Wistar) of average initial weight of 62 ± 3 g (offsprings of 35 days) were used in the experiments of model I and II (total 220 rats).

Diets - the components of diets in g/100 g we the following:

1. Control-diet (Co)
   Casein 25.0, complete as reference(5).
   The animals were fed ad libitum.

2. Energy-restricted diet (R)
   The same Co composition, but restricted to 50% of the average total intake that was consumed by control group. Restricted at 50%.

Intestinal experiment design

The animals were fed for 15 days with the different diets. After an overnight fasting the animals were anesthetized with ether, the abdomen was opened and a segment of the small intestine was isolated by two ligatures: the first one at the Treitz, and the second one just at the ileum-cecum valve, Through a small opening just below the Treitz-tie a narrow polyethylene tube was inserted and 1 ml of the hyperosmolar solution (NaCl, or mannitol) was gently introduced into the lumen. The tube was than retired under the protection of new tie in order to avoid solution reflux. Immediately the abdomen was closed by suture and the animal left to wake up.

After the programmed period of time, the rat was anesthetized again with ether, and the whole small intestine between ties was removed. Its contents were squeezed out into a volumetric tube(5). The intestinal collected volume was measured and completed to 10 ml with de-ionized water, filtered in paper and kept at 4° C till determinations.

Determinations

Sodium by Flame-Photometer (Evand Electroselectelenium); chloride by the reaction with AgNO3 and KSCN using ferric alumen as an indicator(11). Osmolality by the Fiske osmometer (model G.66).

Model I

Rats were fed with R diet for 15 days, when they attained around 80 g of corporal weight. The purpose of this experiment was to determine the period of time of maximum net secretion of sodium after introduction of hyperosmolar NaCl solution in the small intestine of the above mentioned animals. Periods of 5 up to 70 min were tried. Each period was essayed in 10 rats. The maximum net secretion period was called “maximum accumulation period” (MAP). A group of 10 rats were fed Co diet in order to determine their daily ad libitum food intake (total 80 rats).

Model II

Rats were fed R diet for 15 days. As normal pattern reference, animals fed Co diet were used. At the established MAP, cholinergic, anticholinergic and metabolic inhibitor drugs, isolated or intercorrelated were used as a tool for the interpretation of the involved
mechanisms. The hyperosmolar solutions used were NaCl or mannitol (900 mOsm/kg) (10 animals/group, total 140 rats).

RESULTS

Model I

Different periods of time were studied in order to determine the moment of the maximum net secretion (accumulation) of Na⁺ and fluid in the small intestine of malnourished rats as an effect of the hyperosmolar challenge of NaCl (900 mOsm) (Table 1, Fig 1). Since the first minute there was a net secretion of sodium for 20 min, and the MAP occurred at 10 min. Nevertheless there was a net absorption of Cl⁻ since 5 min. A net absorption for Na⁺ was observed only after 30 min, when osmolality reached a value of 325 mOsm/kg. Accumulation (J net) was taken from the differences between initial and final luminal content based on our previous observations (not published) that rats after an overnight fasting presented insignificant [Na⁺] concentration in the intestinal content.

Model II

In order to collect more informations about the possible mechanism of intestinal net secretion of sodium and fluid under hypertonic perturbation, animals were previously injected with i.m. dose of a cholinergic Mch solution, simultaneously or not with A or D drugs as described in Material and Methods. This study was performed under the hypertonic effect of 900 mOsm/g solution of NaCl or mannitol, in 10 min. A control group was maintained for comparation. The average body weight variation of both groups: Co and R, are presented in Table 2.

In Table 3 are shown the results of sodium and chloride accumulation.

Figure 1 – Secretion and absorption of sodium and chloride from NaCl, 900 mOsm/kg. Observations from 10 to 70 min
obtained by the effect of mannitol, which represents the secretion), minus the final result obtained after NaCl.

Assuming these calculations, the final luminal content of Na\(^+\) (Na\(^+\) \text{f}) obtained was:

$$\text{Na}^+ \text{f} = \text{Initial} + \text{Jsm} - \text{Jms}$$

As 900 mOsm/kg NaCl solution corresponds to 450 \(\mu\text{Eq}\) of Na\(^+\) and Cl\(^-\) by introducing this value in the above equation:

$$\text{Jms} = 450 + \text{Jsm} - \text{Na}^+ \text{f}$$

The results obtained from these calculations for Na\(^+\) are presented in Fig. 2 and for Cl\(^-\), in Fig. 3.

The Jsm was not affected by the Mch, D or A drugs. However the Jms decreased significantly by the effect of Mch. The previous injections of A or Mch, as well as the D introduction in the intestinal lumen, inhibited the effect of Mch.

In the energy restricted animals (R) the final accumulation of Na\(^+\) was enhanced in relation to Co-diet group, and this action was more evident after previous i.m. Mch.

**DISCUSSION**

Experimental investigation in animals, related with relevant problem of pediatric gastroenterology, as diarrhea, is an important tool, mainly by the possibility to isolate one among several variables.

In the pathophysiology of diarrhea the role of the osmoregulation, although recognized as a relevant phenomenon, it is not yet clearly understood.

New insights regarding hydrosmotic salt effect on epithelial apical membrane, the role of intracellular modulation of secretory

Impairment in jejunal mucosal detected by biopsies from malnourished children suggests that there is a morphological basis for such liability, which structure reminds immature crypt cells (13). With the progress in knowledge of both intestinal transport and secretion mechanisms the pathophysiology of diarrhea become more understandable in the last decades.

The present investigation has been carried out in order to study the pattern of the intraluminal small intestinal accumulation of fluid and sodium in normal and malnourished rats.

Two different experimental models were sequentially performed as an approach to this goal.

### Model I - In malnourished rats

Net absorption of sodium occurred after 20 min, when the intraluminal osmolality decreased from 900 to 3588 mOsm/kg. KAWAKAMI et al. (12) detected sodium net secretion with perfused solution of 370 mOsm/kg. However the ion chloride was absorbed from the very beginning, suggesting that sodium efflux must be combined with the efflux of another anion than chloride. The intraluminal contents became isotonic only after 30 min.

### Model II

The second experiment was performed with hyperosmolar challenges for 10 minutes. As a tool to speculate more about the mechanisms involved, some factors were introduced as Mch. Mch is a p-sympathicomimetic drug, and as it was observed by the results presented in Table 2, it increased the final net secretion of Na⁺ and Cl⁻.

The efflux was assumed as the results obtained by the experiments performed with mannitol which is not absorbed by the intestine,
and so maintaining the hyperosmolality in the lumen for a longer period than NaCl. If the efflux was not changed by the factors essayed (Mch, A or D) but the net accumulation was impaired, this fact suggests that the influx, or the intestinal absorption was altered in these situations. As the Na⁺ and Cl⁻ accumulation in basal situation were of 78 µEq and 2.2 µEq, respectively, and after Mch i.m. injection these results were higher: 144 and 77.5 µEq, it is possible to conclude that the intestinal absorption of these ions were reduced (Table 2, Fig. 1), and taking in account that the Mch effect was inhibited by A, probably the Mch effect occurred by a cholinergic pathway. But-D—also behaved as Mch inhibitor, and so, it is suggested that Mch acted through an active mechanism inhibiting the intestinal absorption of Na⁺ and Cl⁻, perhaps with cellular mediators.

ISAACS et al.¹⁹ found that cholinergic agents decrease absorption causing secretion across the epithelium while anticholinergic drugs increase absorption and probably its action occurred mainly in the crypt region²¹, perhaps mediated by VIP and AMPc, involving adrenergic receptors²⁵.

Dinitrophenol enhanced the Cl⁻ absorption (Table 3) and probably this was a results of the decreased electrical potential difference (pd) between the two compartments, lumen and blood observed in our previous, not published investigations.

According to studies of JACKSON¹⁰, the Na⁺ net efflux may be originated from unabsorbed sodium initially present in the lumen, or from Na⁺ of the extracellular space of the unstirred layer of fluid or after exit from the tissue itself; it could also possible to be derived directly from a vascular to lumen movement by an osmolar intestinal perturbation.

It was detected a significant increase in the final net secretion or accumulation of sodium, both with or without Mch i.m. injection, remarkable in energy restricted (R) in relation to Co animals.

The fact that the animals under energy restriction (R) presented more evident “net secretion” could be assumed as a final result of decreased re-absorption of the secreted sodium. It is possible to suggest that energy restriction delays the intestinal sodium absorption and this effect could be one of the factors that induces diarrhea in malnutrition. Hydragogue drugs in certain concentrations appear to have the ability to make the intracellular junctions leaky and then standing osmotic gradient cannot be maintained further¹⁷. FLEMING⁷ says that rats deprived of protein have been shown to have increased mucosal permeability to ferritin and adenovirus raising the possibility of a functional deterioration of intracellular functions. NZEGWU and LEVIN¹⁶ detected in rats an increase of the intestinal secretion in malnutrition, and this effect was perturbed by calcium but not by AMPc.

The use of rice-based oral rehydration reduction secretions in intestinal crypts through reducing cAMP¹⁰ and probably by actively inhibiting the chloride channel⁹ must be well evaluated before its adoption as the preferred oral rehydration solutions.

In the present study it is possible that the imposed hyperosmolar load to energy deprived rats could slow tight intercellular junctions.

SPECULATION

As a speculation it is possible to suggest that in the malnutrition, an intestinal challenge (as hyperosmolality) induces more secretion than in normal nutrition because of the reduced capacity of absorption. Other factors are involved in the accumulation of Na⁺ and fluid as cholinergic or secretory mediators. If this could be extrapolated to human beings, it would possible to suggest that malnourished children are more vulnerable to intestinal challenges as hyperosmolality and modulators of secretion developing diarrhea easier than normal ones.
