ALTERATION OF TASTE BUDS IN EXPERIMENTAL CIRRHOSIS. Is there correlation with human hypogeusia?

Sabrina Alves FERNANDES¹, Silvia BONA²,³, Carlos Thadeu Schmidt CERSKI⁴, Norma Possa MARRONI²,³,⁵,⁶ and Claudio Augusto MARRONI¹,³,⁷

ABSTRACT - Background - The inherent complications of cirrhosis include protein-calorie malnutrition and micronutrient deficiencies. Changes in taste are detrimental to the nutritional status, and the mechanism to explain these changes is not well documented in the cirrhotic patients. Objective - To evaluate the taste buds of cirrhotic rats. Methods - Fourteen male Wistar rats were evaluated. After 16 weeks, the liver was removed to histologically diagnose cirrhosis, and blood was collected to perform liver integrity tests. The tongue was removed for histological examination and immunohistochemistry using antibodies against protein gene product PGP 9.5 and the sweet taste receptors T1R2 and T1R3. Morphological changes were determined by scanning electron microscopy. Serum zinc levels were measured. Results - The cirrhotic animals, but not the control animals, exhibited zinc deficiency. In both groups, there was positive immunoreactivity for type II and III cells and T1R2 receptors. The cirrhotic animals had no immunoreactivity for T1R3 receptors. Scanning electron microscopy analysis of the cirrhotic group revealed a uniform tapering of the gustatory papillae. Conclusion - In conclusion the experimental cirrhosis model mimicked the biochemical and histological parameters of human cirrhosis, therefore enabling a study of the gustatory papillae and taste buds.
The human tongue is covered with gustatory papillae that have specific functions (taste receptors and signalling). The papillae allows to differentiate the sweet, bitter, sour, salty and umami flavours. Papillae can be circumvallate, fungiform, filiform or foliate, and they are all distributed on the back of the tongue. In humans, changes in taste may exacerbate PCM related to cirrhosis.

It is possible to detect changes in tongue structure that may indicate the pathophysiological process of hypogeusia. There are four types of cells (I, II, III and IV) in the gustatory papillae. These cells, especially types II and III, are responsible for the transduction of the taste signal to the brain. There are four types of cells (I, II, III and IV) in the gustatory papillae (except for filiform papillae) that enable the identification of changes in taste perception.

The T1R family of hetero-oligomeric taste receptors comprises three specific G protein-coupled receptors, T1R1, T1R2 and T1R3, that have distinct expression patterns. By studying these receptors, potential alterations in taste perception can be identified.

To date, there have been no morphological and/or histological analyses of the tongues of cirrhotic patients, despite hypogeusia being a common complaint of these patients. Carbon tetrachloride (CCl4) is a hepatotoxic drug that is widely used in experimental studies of hepatic cirrhosis because its effects mimic human cirrhosis.

In this study, we hypothesised that morphological and/or histological alterations occurred in the gustatory papillae of cirrhotic patients. However, performing tongue biopsies of cirrhotic and control patients was not feasible; therefore, we analysed the tongues of cirrhotic rats, which exhibited morphological and histological structures similar to the human tongue.

In this study, we aimed to correlate the changes related to PCM and cellular deficiencies with the alteration of the gustatory papillae structure in CCl4-induced cirrhotic animals.

**METHODS**

Fourteen male Wistar rats weighing between 200 and 250 g from the State Foundation for the Production and Health Research (Fundação Estadual de Produção e Pesquisa em Saúde - FEPPS) were utilised. During the experiment, the animals were housed in the Animal Experimentation Unit of the Research Centre at the Teaching Hospital of Porto Alegre (Hospital de Clínicas de Porto Alegre - HCPA) in a 12-hour light/dark cycle (light from 7:00 to 19:00) and at a temperature of 22 ± 2°C. The animals were randomly divided into two experimental groups: control (CO) and cirrhotic (CCl4).

The CCl4 dose, at the end of week 16, was administered on the following schedule: 10 doses at 5 day intervals. The animals were sacrificed 2 days after the last CCl4 dose, at the end of week 16.

All the procedures were performed according to the guidelines recommended by the Research Ethics Committee of HCPA, and the animal care followed the recommendations of the Principles of Laboratory Animal Care formulated by the National Society for Medical Research and the Guide for the Care and Use of Laboratory Animals published by the National Institutes of Health. After 27 doses, the animals were anesthetised with an i.p. injection of xylazine (50 mg/kg) and ketamine (100 mg/kg). Blood samples were collected via the retro-orbital plexus to analyse the liver function.

After sacrifice, the abdominal region was shaved, and a midline laparotomy was performed to collect the liver and the tongue of the animals.

**Serum biochemical analysis**

Blood samples obtained from the retro-orbital plexus were utilised to evaluate serum aspartate aminotransferase (AST), alanine aminotransferase (ALT) and alkaline phosphatase (ALP) levels, which were expressed in U/L and measured using routine laboratory methods at HCPA.

**Bioelectrical impedance analysis**

To measure total body resistance (R) and total body reactance (Xc), a phase-sensitive tetrapolar impedance analyser (Biodynamics BIA 450E) was utilised with hypodermic needles as electrodes. The rats were anesthetised and placed in a prone position on a non-conductive surface to eliminate interference from the electrical induction. On the midline, source electrode 1 was placed at the anterior edge of the orbit, and source electrode 2 was placed 4 cm from the base of the tail. Detector electrode 1 was placed at the anterior opening of the ear, and detector electrode 2 was placed in the middle of the rat pelvis. The analysis was performed in two phases, the initial phase (time 1) and the final phase (time 2).

**Hepatic tissue lipid peroxidation measurements**

Frozen hepatic tissue from each rat was homogenised in ice-cold phosphate buffer (140 mM KCl and 20 mM phosphate, pH 7.4) and centrifuged at 3,000 rpm for 10 minutes. Oxidative stress was determined by measuring the concentration of aldehydic products (malondialdehyde (MDA)) using thiobarbituric acid reactive substances (TBARS). The absorbance (535 nm) of the supernatant was measured by spectrophotometry, and the values were expressed as nmol/mg protein.

**Zinc measurements**

The serum zinc concentration was measured using a Zinc Assay Kit (Abnova Corporation, Taipei City, Taiwan). The absorbance (425 nm) of the supernatant was measured by spectrophotometry, and the values were expressed as µg/dL.

**Histology**

A piece of the liver and of the tongue from each animal was trimmed and fixed by immersion in 10% buffered formalin.
for 24 hours. The blocks were dehydrated in a graded series of ethanol and embedded in paraffin wax. Serial 3-mm sections were stained with picrosirius (liver tissue) and with H/E (tongue tissue). Five sections from each sample were analysed by two independent pathologists with no prior knowledge of the animal groups.

**Scanning Electron Microscopy**

The dorsal region of the tongue was collected and immersed in a fixative solution containing 4% glutaraldehyde. The samples were dehydrated in a graded acetone series: 30%, 50%, 70%, 95% and 100%. A CPD 030 Critical Point Dryer (Leica Microsystems, Buffalo Grove, IL) was utilised to remove moisture from the samples and to reach the critical point.

The metallisation was performed with a gold/palladium alloy. The samples were covered with an approximately 15-nm layer using a Metalizer Med 020 (Leica Microsystems). Images were captured with a Philips XL20 Scanning Electron Microscope at 40-800X magnification.

The taste buds were counted by pathologists who were blinded to the groups. The buds in each field were counted, and the mean was calculated for each sample. Image-Pro Plus (Media Cybernetics, Bethesda, MD, USA) was utilised to determine the diameter of the gustatory papillae and the taste buds.

**PGP 9.5, T1R2 and T1R3**

The expression of PGP 9.5, T1R2 and T1R3 in the tongue was determined by immunohistochemistry. Antigen recovery was performed using citrate buffer at 100°C, and endogenous peroxidase activity was blocked by incubating the slides at room temperature with absolute methanol containing 3% hydrogen peroxide. The slides were preincubated with 10% rabbit serum at room temperature to block potential undesirable reactions with the secondary antibody. The slides were incubated with polyclonal rabbit antibodies against PGP 9.5, T1R2 or T1R3 (Santa Cruz Biotechnology, Santa Cruz, CA, USA) overnight at 4°C followed by an incubation with the secondary antibody for 1 hour at room temperature. After 60 minutes at room temperature, the slides were treated with EnVision reagents (tongue tissue). Five sections from each sample were analysed using a microscope equipped with a digital camera to capture the images using Image-Pro Plus (Media Cybernetics).

**Statistical analysis**

The data were stored in Excel, and the statistical analyses were performed using SPSS (Statistical Package for Social Science) version 18.0. The results are expressed as the mean ± standard deviation (SD). Student’s t-test was utilised to compare the intragroup variables for paired samples and the intergroup variables for independent samples. A 5% level of significance was adopted (P≤0.05).

**RESULTS**

After 16 weeks, we obtained histological confirmation of cirrhosis in all the treated animals; there was no cirrhosis in the control animals. One animal was lost due to death before 16 weeks. The animals were randomized according to the phase angle.

In addition to the histological evidence, the cirrhotic animals displayed significant changes in liver function (AST, ALT and ALP), indicating the presence of liver damage. The zinc levels were lower in the CCl4 group than in the control group (Table 1).

The results are expressed as the mean ± SD. AST: aspartate aminotransferase, ALT: alanine aminotransferase, ALP: alkaline phosphatase; TBARS: substances reactive thiobarbituric acid.

In the lipid peroxidation analysis using TBARS, we observed an increase in lipid peroxidation in all the CCl4-induced cirrhotic animals (P=0.05).

Table 2 presents the body weight data for the control and cirrhotic (CCl4) animals at times 1 (initial) and 2 (final) and the PA measured by bioelectrical impedance analysis at the same timepoints.

In analysing the initial (time 1) and final (time 2) timepoints, we discovered that the control group gained more weight than the CCl4 group (Table 2).

The PA was evaluated at the same timepoints (times 1 and 2). There was a statistically significant difference in the CCl4 group between times 1 and 2, as evidenced by the 2-degree decrease from the initial value to the final value.
Histological analysis of the rat tongues

The initial histological analysis of the liver (Figure 1A and 1B) structure was performed using Picrosirius staining. The histological analysis of the rat tongue structure was performed using H/E (Figure 2A and 2B). This revealed a significant reduction in FiP in the cirrhotic animals compared with the control animals (Figure 2A and 2B).

SEM analysis of the morphological structure of the tongue revealed that tapering of the gustatory papillae occurred, particularly in the base diameter and the apical region, in the CCl₄ group (Figures 3A and 3B). Compared with the control animals, the taste buds in the cirrhotic animals displayed morphological changes (Table 3).

In the animals in the cirrhosis group, some tongues had only one taste bud per field, whereas others contained no taste buds. In the control group, the presence of taste buds per field ranged between 2 and 6.

The immunohistochemical analysis of the innervation of the gustatory papillae using a PGP 9.5 antibody revealed that the control and CCl₄ animals had fungiform papillae (FuP) and FiP in the dorsal region of the tongue.

An immunohistochemical analysis of the T1R receptor family (T1R2 and T1R3) in the gustatory papillae of rats was performed to determine the potential for the sweet taste. T1R2 receptor immunoreactivity was observed in both groups.

There was positive immunoreactivity for T1R3 receptor in the control animals but not in the cirrhotic animals.

**DISCUSSION**

The classic CCl4-induced cirrhosis model is widely accepted in the literature because it has similar characteristics to those of human cirrhosis.

AST and ALT are enzymes that are sensitive to hepatocellular injury. The release of large amounts of these enzymes into the bloodstream is associated with centrilobular necrosis, degeneration, and decreased liver function. In our study, we observed a significant increase in the liver enzyme levels in cirrhotic animals, confirming what has been previously reported.

Zinc is hepatoprotective and required for ALP activity. Zinc is critical to a large number of structural proteins, enzymatic processes, and transcription factors. Zinc deficiency can result in a spectrum of clinical manifestations, such as poor appetite, loss of body hair, altered taste and smell, testicular atrophy, and immune dysfunction, and diminished drug elimination capacity. These are common symptoms in patients with chronic liver diseases, especially liver cirrhosis. Reinforcing the characteristics of this metal, low zinc levels have been observed in cirrhotic animals, and this was confirmed in the present study.

The CCl4-induced cirrhosis model involves various signaling pathways that result in liver injury; this was confirmed in this study by the TBARS values that indicated a relationship between CCl4-induced changes in the liver parenchyma and the formation of reactive oxygen species (ROS) by the hepatic microsomal system. Potentially through the formation of trichloromethyl (CCl3•) and trichloromethyl peroxide (CCl3OO•) radicals. This oxidative process causes cellular damage and may increase ion permeability and membrane and structural disintegration, which can be measured by bioelectrical impedance analysis (the PA).

The reduced PA in the cirrhotic animals was accompanied by an increase in liver enzyme levels and in lipid peroxidation. The body structure of the cirrhotic animals changed as they lost weight.

The cirrhotic animals exhibited body asymmetry resulting from the development of ascites, a symptom that is characteristic of cirrhosis. This change in body composition difficult the determination of the actual nutritional status of the analysed organism when conventional methods, such as anthropometric measurements, are utilised that are based primarily on the amount of body fat.

The PA has been used as a diagnostic factor that assesses cell functionality, and it is associated with other indices that are indicative of the health status. Currently, there have been no studies using this method to evaluate animals.

Cells in the nerve plexus in taste buds are divided based on function into type I, II, III, and IV cells. Only type II and III cells are responsive to stimuli and are called “light” cells. Type II cells receive a stimulus and transmit the signal to type III cells, which form a synapse. In 1982, Nagy et al. demonstrated that there are nerve fibres in the fungiform and circumvallate papillae of rats and that it is possible to record them.

We confirmed these findings by identifying nerve fibres in the FuP in both animal groups. Yee et al. reported that PGP 9.5 immunoreactivity in the gustatory papillae indicated the presence of type III cells.

Five types of taste have been described: in this study, because of the disease characteristics, we chose to analyse the sweet taste because it is linked to a higher percentage of daily caloric intake. The sweet taste is present in all types of gustatory papillae, and its response to stimuli is similar in different mammals.

The sweet taste can be detected via the combination of two receptors (T1R2 and T1R3) that determine the function of the heteromeric T1R receptor. T1R receptors are G protein-coupled receptors (GPCRs); class C GPCRs have a long N-terminus, similar to metabotropic glutamate receptors, GABA receptors, and calcium signal receptors.

Hoon et al. reported in 1997 that the majority of T1R1 receptors are expressed in FuP and are rare in circumvallate papillae. In contrast, T1R2 are poorly expressed in FuP but are expressed in all circumvallate papillae. T1R3 are expressed in both papillae types. We did not observe T1R3-immunoreactive cells, which would mediate the sweet taste, in the cirrhosis group.

In 2003, Kim et al. compared the signalling activity of circumvallate papillae in FuP and determined that FuP can play the same role in responding to sweet stimuli.

In our study, using various techniques, we observed thinning of FiP in the cirrhosis group, which would impair the salty taste. The salty taste is detected directly by Na+ permeability in the apical region of the papilla, causing cell depolarisation to perceive the taste. When there is a thinning of the papillae or they have a decreased diameter, sodium comes into contact with other structures in the dorsal region of the tongue, causing a gradual loss of papillary structure because of a continuous imbalance.

Sweet taste aversion and salty taste intolerance are the two symptoms related to taste that are commonly mentioned by cirrhotic patients, and the changes in the gustatory papillae of cirrhotic animals may play a role in dysgeusia.
CONCLUSION

The experimental cirrhosis model induced by the intra-peritoneal injection of CCl₄ mimicked the biochemical and histological parameters of human cirrhosis. However, we know that xenobiotics may alter the conformity of some cells, these may be the taste buds. In the present study, it was possible to determine that cirrhotic rats present significant alterations in the gustative papillae mainly related to sweet and salt taste. Further studies are needed, such as cirrhosis by ligation of bile duct, to associate this like change to cirrhosis.
