CORRELATION BETWEEN THE NEONATAL EEG AND THE NEUROLOGICAL EXAMINATION IN THE FIRST YEAR OF LIFE IN INFANTS WITH BACTERIAL MENINGITIS

Adrián Poblano\textsuperscript{1,2}, Roberto Gutiérrez\textsuperscript{2}

ABSTRACT - Objective: To assess the contribution of neonatal electroencephalogram (EEG) and its correlation with the neurological examination at age of 9 months in newborns with bacterial neonatal meningitis. Method: Twenty seven infants were studied with positive cerebrospinal fluid (CSF) culture for bacteria. We used the worse EEG result during acute phase of meningitis, and performed neurologic follow-up after discharge from hospital. Background cerebral activity was classified as normal or mildly, moderately, or markedly abnormal. Neurologic examination outcomes was classified normal, mild abnormalities, moderate abnormalities and severe abnormalities. Results: EEG performed in the neonatal period during acute bacterial meningitis predicts adverse outcome early at age of 9 months, and had a significant correlation with cephalic perimeter and active tone alterations. Conclusion: Neonatal EEG is useful for predicting abnormal outcomes, especially cephalic perimeter and active tone abnormalities at 9 months of age in infants with bacterial neonatal meningitis.

KEY WORDS: bacterial meningitis, electroencephalography, neurophysiologic development, neurologic examination, infants, preterm newborns.

Newborn infants (especially premature infants) are susceptible to bacterial infections and may develop primary meningitis or suffer a bacterial attack-associated neuroinfection\textsuperscript{1}. Bacterial meningitis in newborns infants remains as a serious disease with significant long-term neurological morbidity\textsuperscript{2,3}. Prediction of outcome is important in decision-making to provide information to parents, and for identification of subjects requiring close intervention and early follow-up. Clinical evaluation includes neurological examination, cerebrospinal fluid (CSF) culture, neuroimaging studies and neurophysiological studies, such as the electroencephalogram (EEG) and evoked potentials.

In the newborn, EEG provides an extremely useful non-invasive test for brain function. The degree of background activity abnormality has proved to be a predictor of long-term neurologic outcome\textsuperscript{4}.
The goal of this study was to assess the contribution of neonatal EEG and its correlation with the neurological examination during the first year of life in clinical follow-up (age 9 month) of newborns with bacterial neonatal meningitis.

**METHOD**

**Patients** – Subjects were selected from the Neonatal intensive care unit (NICU) at one of the main tertiary-level centers for newborns medical care in Mexico City. All infants with a diagnosis of bacterial meningitis during two years period were identified by review of their medical records. Newborns were included in this study if they met the following criteria: 1) positive CSF culture for bacteria, 2) EEG obtained in the neonatal period during acute phase of meningitis, and 3) neurologic follow-up 9 months after discharge from hospital. The following data were extracted from the infants’ medical charts: age and weight at birth, gender, one and five minutes Apgar scores, and Silverman-Andersen score in search for respiratory distress, conceptional age at EEG recording, perinatal neurological complications (i.e. asphyxia, intraventricular hemorrhage, coma, seizures), CSF values, bacteria identified in cultures, results of cranial ultrasounds (US), computed tomographic (CT) scans, and neurological examination. This study was approved by the Ethics and Research Committee of the Institute and informed consent was obtained from the newborns’ parents.

**Electroencephalogram (EEG)** – Twelve infants (12/27) were studied by more than one EEG recording. We used the worse EEG results performed during acute phase of disease, during sleep state in the NICU during a session of approximately 45 min after feeding or until a complete active, slow, and indeterminate sleep cycle was recorded. The scalp was cleaned with alcohol, and impedance of electrodes was always <5 kilo-ohms. Recordings were obtained on a digital 22-channel electroencephalograph-polygraph (Nicolet, Madison, WI, USA) and consisted of 16 EEG channels, one electromyogram channel placed on the chin, two channels for left and right eye movements, an additional channel for electrocardiogram (EKG) and two channels for respiration (on nose and chest). Gold cup electrodes were placed with electrolytic paste and head wrapping with tape strips. Bipolar montage was used as follows: F1-F3, F3-C3, C3-P3, P3-O1, F2-F4, F4-C4, C4-P4, P4-O2, F1-F7, F7-T3, T3-T5, T5-O1, F2-F8, F8-T4, T4-T6, and T6-O2. Sensitivity was 7.5 μV/mV, band pass filters were set between 0.1 and 35 Hz. The infant’s behavioral state and all movements of the child during the examination were recorded by the technician and were scored in 30-sec epochs according to Prechtl criteria. Observations included eyes open-closed, eye movements, body movements, jerks and twitches, starting, sucking movements, vocalizations and respiratory irregularities such as sighs, pauses and apnea. Careful interpretation was performed off-line. Brain waves present in the EEG were divided into delta (0.1-3.5 Hz), theta (4-7.75 Hz), alpha (8-13 Hz) and beta (14-35 Hz) rhythms. Brain activity was visually and topographically mapped on frontal, central, parietal, occipital and temporal areas, additional details have been published elsewhere. Background cerebral activity was classified according to Klinger et al. criteria as normal or mildly, moderately, or markedly abnormal (Table 1).

**Neurological examination** – Infants were examined in the High-Risk Newborns Follow-up Study of Mexico City. Age at examination was corrected at 40 weeks of gestational age in the case of premature infants. Examinations were performed in clinically routine fashion during follow-up every 3 months during the first year of life by a pediatric neurologist. All examinations were performed with the infant undressed in a warm room in states 3 and 4 according to Prechtl classification. The test included several categories such as: cranial assessment, abnormal eye signs, sensory function, posture and spontaneous motor activity, passive and active tone, primitive and tendon reflexes and postural reactions. The result was considered abnormal when one or more indicators were non-satisfactory. Although Amiel-Tison warns that neurological examination cannot be quantitatively measured, responses were scored on a 0, 1 and 2 scale to compare with results regarding appropriateness for postmenstrual age as optimal response. Outcome was classified as follows: 1) normal, 2) mild abnormalities including abnormalities of tone and excitability but no central nervous system (CNS) depression and no seizures, 3) moderate abnormalities of tone with signs of CNS depression (i.e. minimal monoparesis, controlled seizures, arrested hydrocephalus, poor interaction, hyporeflexia) and one or two isolated seizures, and 4) severe abnormalities including repeated seizures associated with overt CNS depression (i.e. hemiplegia, quadriplegia, uncontrolled seizures, hydrocephalus).

**Data analyses** – We calculated 80% power of detecting differences in means between groups after Chequer et al. and Klinger et al. data. We performed descriptive analyses to determine arithmetic mean and standard deviation (SD) for continuous variables and percents for qualitative variables. We conducted analyses of variance test to compare quantitative clinical characteristics between groups with severity of alteration in neonatal EEG, Tukey post-hoc test was used to identify differences between groups. Results between neonatal EEG and neurologic examination

were compared by $\chi^2$ test. We carried out binomial logistic regression analyses between neonatal EEG results and neurological examination at 3, 6, and 9 months. *Alpha* value determined for accepted significance *a priori* was $\leq 0.05$. Neonatal EEG sensitivity and specificity for predicting abnormalities in neurologic examination were calculated from a 2 x 2 contingency table.6

**RESULTS**

Twenty seven patients were studied: average maternal age at the birth of the infant was 27.59±5.41 years (range, 17-39 years). Fourteen mothers (50%) had one previous gestation, for seven mothers (25%) it was the first pregnancy, and the remaining mothers had two or more gestations (25%). Two infants (7%) were born vaginally and 25 (92%) by cesarean section.

Fifteen infants were male (55%) and 12 female (44%). Clinical characteristics of infants are shown in Table 2. Fourteen infants (51%) were born at age <32 weeks of gestation (wG), 10 between 32 and 36 wG (37%) and three with 37 or more wG (11%). Sixteen subjects (59%) had birthweight <1,500 g, eight were between 1501 and 2500 g (29%), and three (11%) infants weighed 2,501 g or more at birth. Height at birth ranged from 26 and 50 cm, while cephalic perimeter had a range of between 24 and 39.3 cm. Apgar score at 1 min (Apgar 1) ranged between 2 and 8, and 5-min Apgar (Apgar 5) score had a range of between 4 and 9, and Silverman-Andersen score ranged between 5 and 2.

Bacterial cultures reported *Staphylococcus aureus* and *Staphylococcus coagulase-negative* in seven cases of each (25%). Group B *Streptococcus* was positive in four subjects (14%), Group D *Streptococcus* was positive in two cases (7%), and different bacteria in each of the seven remaining cases (3%). Antibiotic treatment included a combination of vancomycin-cephotaxim in 20 subjects (74%), vancomycine alone in four (14%) and an ampicillin-amikacin combination in three cases (11%). Average hospitalization days was 54.4±29.4 days with range of 10-120 days.

EEG recordings during neonatal period were normal in nine patients (one third of the sample, 9/27 of patients), while eight were mildly abnormal (8/27), nine were moderately abnormal (9/27), and one was markedly abnormal (1/27). Clinical characteristics comparison of infants by EEG alteration severity detected differences in Apgar 5 score between groups, and post-hoc analyses revealed that infants with moderately and markedly abnormality had significantly lower scores (p=0.005). Neurological examination was performed in 26 infants at 3 and 6 months of age, and in 27 infants at age 9 months; results are show in Table 3.

No statistical differences were found when overall results were compared from both the neurologic examination and neonatal EEG (p=0.08). Significant association was found between neonatal EEG result and cephalic perimeter alteration at 3, 6, and 9 months using normative data from our country (Wald score=11.40, 9.96, and 10.42; p=0.001, 0.002, and 0.001 respectively) and active tone at 9 months (Wald score=8.94; p=0.003). EEG sensitivity and specificity for predicting change in neurologic examination at 9 months of age were 72% and 44% respectively.

CT was performed in two infants and both studies were abnormal, magnetic resonance imaging (MRI) was performed in one patient who had abnormal result. US studies were abnormal in eight subjects (30%), abnormalities found included intraventricular hemorrhage in five patients (18%), and periven-
tricular leukomalacia and hydrocephalous in three subjects each (11%).

**DISCUSSION**

We found that an EEG performed in the neonatal period during acute bacterial meningitis predicts adverse outcome early within the first year of life. Few studies have examined the value of neonatal EEG as a prognostic tool in patients with bacterial neuroinfection.

Watanabe et al. studied EEG-polygraphically in 29 newborns with meningitis, and visual and auditory evoked potentials were also obtained in some infants: clinical findings correlated with outcomes. EEG background activity was a good prognostic tool but could not indicate complication type, although persistent abnormalities correlated with severe brain injury. Unfortunately, the study included infants without culture-proved meningitis.

Chequer et al. retrospectively studied 29 infants with culture-proven meningitis; they found that degree of EEG background activity abnormality proved to be a good predictor of long-term neurologic outcome. Infants with normal or mildly abnormal EEG have normal outcomes, whereas those with markedly abnormal EEG died or manifested severe neurologic damage at follow-up.

Klinger et al. studied 37 infants during the neonatal period and 21 had adverse outcomes; nine died and 12 infants had moderate to severe disability at 1 year of age. EEG background activity and overall EEG description were identified as predictors of adverse outcome; multivariate analysis indicated that the latter was a stronger predictor, with sensitivity of 88% and specificity of 90%. Infants with normal or mildly abnormal EEG had good outcomes, whereas those with moderate to markedly abnormal EEG died or survived with neurologic sequelae. Our data are in agreement with these latter results, although we found lower values of sensitivity and specificity.

Etiologic agents found in our infants sample are in agreement and in partial agreement with those of other studies carried out at other NICUs in Mexico City, but are not in total agreement with other studies performed elsewhere. Thus any consideration with regard to differences in neurological outcomes related with specific bacterial agents must be performed carefully, more research is necessary in the future with larger number of patients and with multicenter samples with clinical, neurophysiological, neuroimaging and microbiological techniques to answer this question.

Correlation between EEG results and results concerning cephalic perimeter and active tone on the neurological examination are reported here for the first time and deserve greater attention in future studies. Correlation between Amiel-Tison examination and outcomes with other methods such as US, EEG, and cerebral function monitoring at 12-15 months of age was reported as good. Neurologic examination sensitivity for detecting infants with abnormal US was 0.97, with EEG 0.89, and with cerebral function monitoring 0.88. Thus combined EEG examination with the clinical Amiel-Tison neurological examination augments probability of detection of early brain damage, as is well known by physicians.

A significant relation between Apgar 5 with severity of EEG abnormalities was found. This finding underlines additive effects of early adverse conditions at birth in infants with CNS infection; this point has been observed in many diseases, such as apnea in infants, and deserve more attention in future research. We suggest that clinicians and investigators must perform a multivariate weighting of each risk-factor, neurological examination, neurophysiologic, and neuroimaging studies, for prediction of neurological sequelae in infants with neonatal bacterial meningitis.

Our patients survived during the acute phase of neuroinfection and during the 9-month follow-up; therefore disease severity could be less than in infants in the samples of Watanabe et al., Chequer et al., and Klinger et al. Infants with normal or mildly abnormal EEG survived without sequelae, and those with moderately and markedly abnormal activity were neurologically abnormal at follow-up. EEG abnormalities included an infant with burst-suppression, and others with slowing of background activity, spikes and slow waves. Seizures occurred in some of these infants, others had intraventricular bleeding-related hydrocephalous in which ventriculo-peritoneal shunt placement was performed and were under control during follow-up period.

Our study had certain limitations including small sample size and selection bias, despite the fact that we calculated sufficient statistical power to detect differences among groups of EEG alteration severity. Nonetheless based on the result of this experience it is our recommendation that EEG recording be obtained early in acute phase of the neuroinfection. We conclude that neonatal EEG is useful for predicting abnormalities in cephalic perimeter and active tone at 9 months of age in infants with bacterial neonatal meningitis.
