ANHIDROSIS AS THE FIRST SIGN OF ROSS SYNDROME

Marcus H.S.B Xavier¹, Fábio H.G. Porto², Gabriela B. Pereira¹, Luiz Peres Quevedo³, Paula M. de Freitas¹, Osvaldo J.M. do Nascimento⁴, Marcos R.G. de Freitas⁴

The Ross syndrome was first described in 1958¹, as a degenerative autonomic nervous system disorder defined by the triad: widespread anhidrosis, diminished deep tendon reflexes, and Adie's tonic pupils¹². The most disturbing symptoms are segmental compensatory hyperhidrosis and heat intolerance. This article reports a 44-year-old male with a 19-year history of progressive anhidrosis with heat intolerance, as the mainly complaint. A segmental patch of compensatory hyperhidrosis was present in the lower abdominal T11–12 dermatomes.

The significance of our case report centers on the recognition of the skin lesions that lead to the diagnosis of an autonomic nervous disease.

CASE

A 45-year-old male presented with a 19-year history of anhidrosis, which first started on the upper limb. It had slowly developed up to the trunk, face and lower limbs, but has spared his lower abdomen, in the position of T11–12 dermatomes. In this place there was a segmental compensatory hyperhidrosis (Figure). He reported severe heat intolerance that obligated him to take frequent cold showers during the day. He complained of feet paresthesias, and impaired taste sensation for sweet. He has no history of postural hypotension, urinary or bowel symptoms, or any sexual disfunctions.

Physical examination revealed an irregular patch of hyperhidrosis, erythema and hypothermia on the lower back, in the T11–T12 dermatomes, and anhidrosis elsewhere (Figure). Neither the affected area nor another area of the skin showed signs of dystrophy or sensory impairment. The deep tendon reflexes were absent in both upper and lower limbs. Pupillary examination showed anisocoria, with the right pupil larger than the left. The right pupil reacted poorly and slowly to light, but the reaction to near sight was preserved. Once constricted, the right pupil remained with a tonic constriction, dilating slowly when the illumination was removed. The remainder of the neurologic examination was normal, including tests for postural hypotension. Nerves conduction study was normal without any evidence of peripheral neuropathy. Tests for sympathetic skin reflexes were absent to stimulation in upper and lower limbs. The Tilt test was normal. The cerebrospinal fluid analysis including VDRL test was normal. The diagnosis of Ross syndrome was made based on the clinical symptoms, neurologic signs, and complementary investigations. The patient was treated symptomatically with emollients and showed some improvement of xerosis after 3 months of treatment. Despite the skin symptom improvement, the heat intolerance obligated the patient to quit his job as a bus driver.

The patient agrees with the submission of the pictures showing the skin lesion. Consent in the form of a signature was received by the authors.

**DISCUSSION**

Ross syndrome was first described by Ross¹, in 1958. It comprises a triad of tonic pupil, hyporreflexia and widespread anhidrosis with or without compensatory hyperhidrosis². Some authors argue that the classic triad was first described ten years earlier, by Hans Hüetlin³. Anhidrosis may be accompanied by other alterations of the autonomic nervous system as cardiac dysautonomia⁴. Nolano et al.² found a complex and progressive involvement of cutaneous sensory and autonomic innervation underlying the impairment of heat production and heat dissipation. This occurs through both loss of sweating and impairment of cutaneous blood flow regulation. The pathophysiology underlying Adie’s pupil is post-ganglionic denervation of cholinergic fibers between the ciliary ganglion and the iris sphincter muscle⁵. Depression of deep tendon reflexes is due to dorsal root ganglionic degeneration and spinal interneuron loss. It has been demonstrated the involvement of unmyelinated epidermal sensory fibers in patients with Ross syndrome, suggesting a degenerative and progressive disorder that involves autonomic, unmyelinated and myelinated fibers⁶.

The course is usually chronic, with a possible expansion of the dyshidrotic area. Natural history is frequently slowly progressive, sometimes as long as 50 years². However, Nagane et al.⁸ have recently described a transitory form of Ross syndrome associated with cytomegalovirus infection, in which the symptoms improved partially with the infection resolution.

The therapeutic options included video-assisted thoracoscopic sympathectomy⁹, iontophoresis¹⁰, local instillation of botulinum toxin type A and 0.5% glycopyrrolate aqueous cream¹¹. The last is effective by its cholinergic receptor antagonistic effects thereby reducing sweat production rather than blocking sweat ducts, as in iontophoresis.
