The utility of omega-3 fatty acids in epilepsy
More than just a farmed tilapia!

ABSTRACT
The epilepsies are one of the most common serious brain disorders and 20 to 30% of people developing epilepsy continue to have seizures and are refractory to treatment with the currently available therapies. Approximately one in a 1000 patients with chronic epilepsy will die suddenly, unexpectedly, and without explanation, even with post-mortem examination and this phenomenon is called sudden unexplained death in epilepsy (SUDEP). Understanding the mechanisms underlying SUDEP may lead to the identification of previously unrecognized risk factors that are more amenable to correction. We discuss here the possible implications of omega-3 fatty acids consumption on SUDEP prevention.

Key words: epilepsy, sudden death, omega-3.

A utilidade do ácido graxo ômega-3 na epilepsia: mais do que uma criação de tilápias!

RESUMO
As epilepsias encontram-se entre as mais sérias doenças neurológicas; 20 a 30% dos pacientes com epilepsia continuam apresentando crises e são refratários às terapias disponíveis atualmente. Aproximadamente um em cada 1000 pacientes com epilepsia crônica irá morrer de forma súbita, não esperada e sem explicação, mesmo com o exame pós-mortem. Este fenômeno é denominado morte súbita e inesperada em epilepsia (SUDEP). Compreender os mecanismos envolvidos nos casos de SUDEP pode levar à identificação de fatores ainda não reconhecidos e passíveis de serem corrigidos. Discutiremos a seguir as possíveis implicações do consumo do ácido graxo ômega-3 na prevenção dos casos de SUDEP.

Palavras-chave: epilepsia, morte súbita, ômega-3.

The epilepsies are one of the most common serious brain disorders and it knows no age, racial, social class, geographic, or national boundaries¹. Several studies have reported that approximately 50 million people worldwide have epilepsy and that between 70 and 80% of people developing epilepsy will go into remission, while the remaining patients continue to have seizures and are refractory to treatment with the currently available therapies²³. Furthermore, 80% of the 50 million people who have epilepsy live in countries with poor resources and this apparent discrepancy between rich and poor countries could be due by higher mortality in people with epilepsy in the developing world than in more affluent countries⁴⁵. In this context, it has been described that each year about one in a 1000 patients with chronic epilepsy will die suddenly, unexpectedly, and without explanation, even with post-mortem examination⁶. In the vernacular of the world of epilepsy, this phenomenon is called sudden unexplained death in epilepsy (SUDEP)⁶. Actually, epilepsy is as-
sociated with a two- to three-fold increase in mortality compared to the general population, and SUDEP is the most important direct epilepsy-related cause of death. To date, a number of associated factors for SUDEP have been assessed in a number of studies but the results are not wholly consistent between them. These include the rese

...toriness of the epilepsy, presence of generalized tonic-clonic seizures, polytherapy with antiepileptic drugs, young age, duration of the seizure disorder ranging from 15 to 20 years, early onset of epilepsy and winter temperatures. Additionally, knowledge of risk factors underlying SUDEP could guide investigations into its pathophysiologic mechanisms. Conversely, understanding the mechanisms underlying SUDEP may lead to the identification of previously unrecognized risk factors that are more amenable to correction. Although different mechanisms play a role in different cases, there are indications that cardiac arrhythmia during and between seizures play a potential pathomechanism for SUDEP. Thus, considering that efforts to prevent and control seizures should be directed towards removing the causes of SUDEP, several experimental and clinical studies have been clearly demonstrated that complementary medical therapies, especially omega-3 fatty acids, are often tried by patients with epilepsy to control their seizures and hence SUDEP. In brief, the first randomized trial of omega-3 supplementation in patients with chronic epilepsy were encouraging, demonstrating a transient effect on seizure control that was not confirmed by other research group, but additional trials are required. Although these results did not totally confirm that omega-3 fatty acids supplementation reduce the frequency of epileptic seizures in patients with refractory epilepsy; they established the safety of omega-3 supplementation in people with epilepsy.

Polyunsaturated fatty acids (PUFAs) docosahexaenoic acid (DHA, 22:6n-3) are major components of membrane phospholipids in brain tissue. The eicosanoids play important roles in neural function including sleep induction, long term potentiation, spatial learning and synaptic plasticity, resolution of inflammation (lipoxins) and anti-inflammatory and neuroprotective bioactivity (di-hydroxy-docosatriene, neuroprotectin D1, formed from DHA). Diets deficient in omega 3 PUFA lead to reduced DHA in the brain and increased turnover of arachidonic acid to eicosanoids, an effect which is overcome by restoring the omega 3 PUFA to the diet.

Studies in mice reported that both omega-3 and omega-6 fatty acids protect cells from oxidative stress and suppress apoptosis and PUFA supplementation may have neuroprotective effects. Also, it has been demonstrated that n-3 PUFA treatment increased BDNF protein levels in the motor cortex of mice, enhances hippocampal neurogenesis, with an increase in the number of proliferating neurons and density of dendritic spines of CA1 pyramidal neurons in the hippocampus.

Similarly, studies had demonstrated that DHA reduced expressions of tumor necrosis factor-alpha, interleukin-6, nitric oxide synthase, and cyclo-oxygenase-2, induced by interferon-gamma, and induced upregulation of heme oxygenase-1 in microglia. Using the pilocarpine model of epilepsy, a valuable tool to study the pathogenesis of temporal lobe epilepsy in human condition, our research group was the first to demonstrate that chronic treatment with omega-3 promotes neuroprotection and positive plastic changes in the brain of rats with epilepsy, with a decreased in neuronal death in CA1 and CA3 subfields of the hippocampus. This could be attributed to n-3 PUFAs ion channel modulation, and anti-inflammatory action.

In vitro studies, DHA has been reported to inhibit epileptiform activity and synaptic transmission mainly through the frequency-dependent blockade of Na+ channels in the rat hippocampus, and to stabilize neuronal membrane by suppressing voltage-gated Ca2+ currents and Na+ channels.

After these research evidences of beneficial effects of omega-3 fatty acids in the brain and clinical reports of transitory seizure control patients with epilepsy should be encouraged to eat fish more frequently. The association between fish consumption and low rates risk of cardiovascular disease has been studied nearly four decades ago with the consumption of seafood diets by Greenland Eskimos, Alaskan Natives and Japanese people residing in fishing villages. Recently, several noncardiovascular actions of fish consumption have also been described, suggesting that a regular diet of fish could be of benefit in many conditions, including various central nervous system (CNS) diseases. Concerning CNS, we need to keep in mind that omega-3 fatty acids (from fatty fish in the human diet) also appear effective on the structure, the biochemistry, the physiology and thus the function of the brain. As we know, the brain is one of the organs with the highest level of lipids (fats). Brain lipids, formed of fatty acids, participate in the structure of membranes, for instance 50% fatty acids are polyunsaturated in the gray matter, 1/3 are of the omega-3 family, and are thus of dietary origin. Thus, seafood (commonly found in fish and fish oil) is the only foods that provide large amounts of omega-3. Fish can be classified into lean fish that store lipid in the liver (eg, cod) or “fatty” (oily) fish that store lipid in the flesh (eg, salmon, tuna, sardines and herring). On the other hand, it is very important to emphasise that some types of fish may contain high levels of methylmercury, PCBs (polychlorinated biphenyls), dioxins and other environmental contaminants. Levels of these substances are generally highest in older, larger and predato-
ry fish\textsuperscript{32,37-39}. So, as the concentration of methylmercury is increased in predatory fish, the best seafood choices are those with nonpredatory characteristics. Anchovies, Atlantic herring, salmon, sardines, and trout have low levels of methylmercury, whereas tuna, shark, tilefish, and swordfish have high levels of methylmercury\textsuperscript{32,37-39}. A study developed by researchers from Wake Forest University School of Medicine characterized the content of favorable and unfavorable polyunsaturated fatty acids (omega-3 and omega-6) found in commonly eaten fish, with closer inspection on the four most commonly consumed farmed fish (salmon, trout, tilapia, and catfish)\textsuperscript{30}. Tilapia is the second (to farmed Atlantic salmon) most widely farmed fish in the world\textsuperscript{30}. Based in all these facts, what we, as neuroscientists, should be thinking about it?

Firstly and most important, the health benefits of the omega-3 in fish have been well documented\textsuperscript{20,40,41}. Concerning CNS and associated disorders, the belief that “fish is brain food” has been held around the world for well over two thousand years\textsuperscript{33,42,44}. Actually, it is clear that fish supplies omega-3 oils, essential for brain and eye tissue development in infants; it remains fundamental to those tissues throughout life\textsuperscript{31,42}. Furthermore, the implications of omega-3 deficiency on the brain are profound and span the entire human life cycle. Beginning in pregnancy, premature birth and its potential neurologic complications may result from omega-3 deficiency\textsuperscript{33,42}. On the other hand, one observation deserves explanation here. After much discussion, consensus was reached on the importance around the balance of omega-6 and omega-3 fatty acids for homeostasis and normal development\textsuperscript{33}. Thus, the ratio of omega-6 to omega-3 is an important determinant of health\textsuperscript{44}. Anthropological evidence suggests that human ancestors evolved on a diet in which the ratio of omega-6/omega-3 was about 1, whereas in the Western diets, the ratio is 15/1 to 17/1\textsuperscript{44}. In these lines, it has been extensively demonstrated that excessive amounts of omega-6 and a very high omega-6/omega-3 ratio, as is found in today’s Western diets, is associated with serious physiological dysfunctions and contributes to the development of several diseases such as heart attacks, thrombotic stroke, arrhythmia, arthritis, osteoporosis, inflammation, mood disorders, obesity, and cancer\textsuperscript{44,45}. In this context, these excessive amounts of omega-6 fatty acids upsetting the balance that was characteristic during evolution when our genes were programmed to respond to diet and other aspects of the environment\textsuperscript{44}. This consideration was recently demonstrated in an elegant study conducted by Weaver and colleagues that developed a dietary intervention strategy in which 27 healthy humans were fed a controlled diet mimicking the omega-6/omega-3 ratios of early humans over 5 weeks\textsuperscript{36}. For that, the authors then looked at the gene levels of immune sig-
