Nontraumatic clival cerebrospinal fluid rhinorrhea

Rinoliquorreia espontânea secundária à fistula de clivus

Cerebrospinal fluid (CSF) fistula is characterized by a leak through a communication between the subarachnoid space (SAS) and the external environment. Three main factors are necessary to be present for the production of a fistula: bone defect, meningeal tear, and pressure gradient.

Spontaneous fistulae, as opposite to the posttraumatic variant, are less common. The ones submitted to a high pressure gradient are usually secondary to tumors or hydrocephalus, whereas the low-pressure gradient type may be related to congenital defects, bone erosion, excessive aeration, or encephaloceles¹.

The characteristics of unilateral leak of colorless fluid through the nostril, varying with postural changes and followed by headache, must not be overlooked. While posttraumatic leaks often heal spontaneously, around 70% of the nontraumatic variant persist, with recurrences after surgical repair ranging from 25 to 87%².

A patient with an upper clivus spontaneous CSF fistula is presented, among only other four previously reported cases.

CASE REPORT

A 49 year-old woman with a history of CSF rhinorrhea since 2002, had been submitted to three different attempts to surgical correction up to 2007, always through bifrontal craniotomies, with episodes of recurrent meningitis. On admission, she had no focal neurological signs except for olfactory loss. Her high blood pressure had always been poorly controlled. Magnetic resonance imaging (MRI) revealed fluid level within the sphenoidal sinus, connected to the pre-pontine cistern, through an upper clival defect (Figure).

She was then submitted to a transnasal endoscopic approach. A bone defect was identified at the upper clivus, which was repaired through the use of nasal septal cartilage secured with a mucosal flap rotation and fibrin glue. After five days, her lumbar drain was removed. She has been followed for the last four years without recurrence.

DISCUSSION

Idiopathic spontaneous CSF rhinorrhea would represent from 14 to 46% of all cases³. Skull base malformation, excessive sinus aeration, primary or secondary empty sella syndrome, and obesity would be risk factors. The association between increased weight and benign intracranial hypertension applied to a thinned skull floor has been speculated as a possible cause³. The origin of spontaneous clival fistulae remains to be elucidated.

Coitero et al.⁴ described the first two cases of CSF clival fistulae, mentioning the diagnostic challenges.

Aside from the primitive synchondrosis, the process of enchondral ossification for clival formation is continuous and does not allow weakened fusion points, which could eventually lead to bone defects⁵.
Coitero et al.\(^4\) suggested that, in one of their cases, repeat-
ed basilar artery pulsations over a thinned bone structure
could have produced the defect. Similar explanation could
eventually be suggested for this particular case, considering
in addition the associated condition of poorly controlled ar-
terial blood pressure.

Advances in technological imaging tools have provid-
ed better facilities for the identification of CSF leaking sites,
whereas improvements in surgical techniques, including the
introduction of skull base endoscopy, have led to better surgi-
cal results\(^5\). However, attempts to explain the pathophysi-
ology of CSF clival fistulae remain speculative.

Patients with primary progressive aphasia (PPA) often evolve
to frontotemporal lobar degeneration (FTLD) syndromes\(^1\), but
the logopenic form of PPA has been found to have Alzheimer’s
disease (AD) pathology and in vivo biomarkers suggestive of
AD\(^2\). We have reported the case of a female right-handed pa-
tient with four years of schooling, who first sought assistance at
the age of 63 years-old for impairments in her speaking fluency.
Her daughter mentioned that two years earlier the patient be-
gan to mumble, struggling to complete sentences, often saying
things out of context, with clear perception that she meant to
say something else. Semantic defects were often present, when
asking for a spoon and pointing to a fork, or changing the names
of her children – though she knew who they were. In the previ-
ous six months, the patient progressively lost the ability to read,
currently writing with difficulty. Lately, she began to show diffi-
culties locating herself in space. Most household tasks were ef-
fortlessly performed, but she could no longer answer the phone
because she could not communicate or take notes, and neither
shop, since her calculating skills had been lost.

Neurological examination was largely normal. The neu-
ropsychiatric testing displayed the following results: a 12-
item neuropsychiatric inventory score of 17 (mostly for
anxiety and sleep disorders), with a score of 8 for caregiv-
er distress; Clinical Dementia Rating of 1.0; score of 9 on
the Mini-Mental State Examination (orientation to time –
2/5; orientation to space – 3/5; immediate memory – 1/3;
calculations – 0/5; recent memory – 0/3; language – 3/9);
score of 1 on the 15-point Clock Drawing Test; she was able
to complete one item of the Rey-Osterrieth Complex Figure
Test, but was not able to recall it; score of 3 on the Boston
Naming Test (15-item short version); abstract thinking was
seriously impaired, while the patient was not able to read
simple sentences, and scored 2 for animals and 4 for fruits
in one minute for verbal fluency tests. She was independ-
ent for activities of daily living (ADL), whereas partially
independent for instrumental ADL. Magnetic resonance
(MR) studies of the brain showed a pattern compatible
with both PPA and AD (Fig 1 and 2).
