ABSTRACT

Neurodegeneration with brain iron accumulation (NBIA) represents a heterogeneous and complex group of inherited neurodegenerative diseases, characterized by excessive iron accumulation, particularly in the basal ganglia. Common clinical features of NBIA include movement disorders, particularly parkinsonism and dystonia, cognitive dysfunction, pyramidal signs, and retinal abnormalities. The forms of NBIA described to date include pantothenate kinase-associated neurodegeneration (PKAN), phospholipase A2 associated neurodegeneration (PLAN), neuroferritinopathies, aceruloplasminemia, beta-propeller protein-associated neurodegeneration (BPAN), Kufor-Rakeb syndrome, mitochondrial membrane protein-associated neurodegeneration (MPAN), fatty acid hydroxylase-associated neurodegeneration (FAHN), coenzyme A synthase protein-associated neurodegeneration (CoPAN) and Woodhouse-Sakati syndrome. This review is a diagnostic approach for NBIA cases, from clinical features and brain imaging findings to the genetic etiology.

Keywords: neurodegeneration with brain iron accumulation; NBIA; clinical features; brain imaging; genetics.

RESUMO

A neurodegeneração com acúmulo cerebral de ferro (sigla em inglês NBIA) representa um grupo heterogêneo e complexo de doenças neurodegenerativas hereditárias, caracterizada pelo acúmulo cerebral de ferro, especialmente nos núcleos da base. O quadro clínico das NBIAs em geral inclui distúrbios do movimento, particularmente parkinsonismo e distonia, disfunção cognitiva, sinais piramidais e anormalidades da retina. As formas de NBIA descritas até o momento incluem neurodegeneração associada a pantothenase kinase (PKAN), neurodegeneração associada a fosfolipase A2 (PLAN), neuroferritinopatia, aceruloplasminemia, neurodegeneração associada a beta-propeller protein (BPAN), síndrome de Kufor-Rakeb, neurodegeneração associada a membrana mitocondrial protein (MPAN), neurodegeneração associada a “fatty acid hydroxylase” (FAHN), neurodegeneração associada a coenzima A synthase protein (CoPAN) e síndrome de Woodhouse-Sakati. Esta revisão é uma orientação para o diagnóstico das NBIAs, partindo das características clínicas e achados de neuroimagem, até a etiologia genética.

Palavras-chave: Neurodegeneração com acúmulo cerebral de ferro; NBIA; sinais clínicos; neuroimagem; genética.

Neurodegeneration with brain iron accumulation (NBIA) represents a heterogeneous group of inherited neurodegenerative diseases, characterized by excess iron accumulation, particularly in the basal ganglia, and to a lesser degree in substantia nigra and adjacent areas¹. NBIA is considered to be a very rare disease group, with a prevalence of less than 1/1,000,000 in general population¹. Common clinical features of NBIA include movement disorders, particularly parkinsonism and dystonia, cognitive dysfunction, pyramidal signs, and retinal abnormalities¹².³

Hunt in 1917 described a case report of juvenile parkinsonism associated with progressive atrophy of globus pallidus¹. In 1922, Hallervorden and Spatz reported a family with five affected sisters

with neuropathological confirmation of lesions of globus pallidus
and substantia nigra. Davidson described in 1954, a case series of
five patients presenting with progressive parkinsonism, dystonia,
and spasticity, associated with pyramidal and pallidal lesions, and
created the term pallidopyramidal degeneration (PPD). However,
this disease was worldwide known as Hallervorden-Spatz syn-
drome (HSS). Julius Hallervorden and Hugo Spatz were German
physicians, who performed several neuropathological studies on
brain specimens of mental retardation persons, executed during the
Third Reich euthanasia program (Aktion-T-4). After confirma-
tion of Hallervorden and Spatz’s involvement in the euthana-
sia program of the Nazi regime in Germany, and the recent neu-
roimaging and genetic discoveries, this syndrome was renamed
NBIA. In 2010, Horstink et al. suggested that PPD was a misno-
er and conclude that the existence of PPD as a distinct noso-
logical entity is doubtful. In 2013, Kara et al. argued that the use
of the term NBIA is not ideal and suggested the term pallidopyra-
midal syndromes (PPS), however NBIA is the most known world-
wide term. To date ten forms of NBIA has been described, eight
with autosomal recessive inheritance, one autosomal dominant
form, and one with X-linked dominant inheritance. The most
common forms are pantothenate kinase-associated neurodegen-
eration (PKAN) (30-50% of NBIA cases), due to mutations in the
PANK2 gene, followed by phospholipase A2 associated neurode-
geration (PLAN) due to PLA2G6 gene mutations, mitochon-
drial membrane protein-associated neurodegeneration (MPAN)
due to C19orf12 mutations, and beta-propeller protein-associated
neurodegeneration (CoPAN) causing SENDA syndrome (static
encephalopathy of childhood with neurodegeneration in adult-
hood) (gene WDR45, chromosome Xp11.23). Probably most of
the case published in the literature as HSS were PKAN. Other
less common forms are fatty acid hydroxylase-associated neuro-
degeneration (FAHN), coenzyme A synthase protein-associated
neurodegeneration (CoPAN), Kufor-Rakeb syndrome (PARK9),
Woodhouse-Sakati syndrome, neuroferritinopathy and acerulo-
plasminemia. The forms of NBIA described to date and the re-
spective gene mutations are listed in Table 1.

Pantothenase kinase-associated neurodegeneration (PKAN)

PKAN is an autosomal recessive disorder characterized
by mutations in the gene encoding a mitochondrial panto-
thenate kinase (PANK2) at locus 20p13-p12.3. It is the most
common disorder of the NBIA group. The classic clinical
presentation of PKAN is characterized by early-onset
(mean age is 14 years - range from 1 to 28y) and rapidly pro-
gressive course. The affected child presents gait impairment
and movement disorders (particularly dystonia and parkinsonism).
Spasticity and brisk tendon reflexes are common. Cognition is frequently impaired.
Retinitis pigmentosa may occur, associated or not with acanthocytes
in blood cells. The majority of individuals (85%) become
wheelchairbound within 15 years after the beginning of
symptoms. Speech and swallowing are affected with dis-
ease progression. Death is usually secondary to respiratory
infections, cardiorespiratory complications, malnutrition
state and, rarely, status dystonicus. Atypical phenotypes with
slowly progressive course have a late onset. Neuropsychiatric
symptoms are common and may be early signs. They include
mood lability, impulsivity, non-specific behavioral changes,
and obsessive-compulsive features.

Brain magnetic resonance imaging (MRI) plays an im-
portant role in the investigation of PKAN since it shows the
‘eye-of-the-tiger’ sign, defined as a medial area of hyperintense
signal within hypointense signal in globus pallidus bilaterally and
best demonstrated on T2WI and SWI (Figure 1). Hypointense
signal may also be observed in the substantia nigra.

There is no current specific therapy to stop disease progres-
sion. Treatment is supportive and intend to relief associated
symptoms. Dystonia and spasticity are usually managed
with anticholinergic drugs, benzodiazepines, botulinum toxin,
oral baclofen and intrathecal baclofen in severe cases. The role
of the brain iron accumulation in the pathophysiology of the
disease remains under discussion, and iron chelation therapy
has been investigated as a disease modifying approach.

Phospholipase A2 associated neurodegeneration (PLAN)

PLAN is an autosomal recessive form of NBIA. The disease
is caused by failure in the ubiquitously expressed
PLA2G6 gene, which maps to chromosome 22q13.1. This gene encodes phospholipase A2 group VI, which may disrupt membrane homeostasis, involved in free fatty acids and lysophospholipids synthesis, resulting in neurodegeneration, atrophy, brain iron accumulation, gliosis and degeneration of the optic pathways. The majority of PLAN cases have early-onset of symptoms, with beginning in childhood. PLA2G6-associated diseases have variable syndromes and may include: classic infantile neuroaxonal dystrophy (INAD), atypical neuroaxonal dystrophy (aNAD) of childhood-onset and PLA2G6-related dystonia-parkinsonism with late onset in adulthood.  

Arq Neuropsiquiatr 2016;74(7):587-596
INAD is characterized by early-onset mental developmental delay, ataxia with cerebellar atrophy, neuropathy and optic atrophy. Patients usually have hypotonia, kyphoscoliosis and limb contractures. The symptoms usually occurs before 2 years old and the progression of the disease is rapid leading to death in the first decade\(^1\)\(^2\). An estimated 50% of patients have abnormal iron accumulation in brain MRI, evolving globus pallidus, dentate nuclei and substantia nigra (Figure 2)\(^1\)\(^0\). Optic pathway atrophy is a relevant clue for the disease\(^9\).

aNAD was previously described as Karak syndrome. This disease is less aggressive than classic INAD. The typical clinical presentation of aNAD include early-onset (older than INAD) ataxia and dysarthria, hypotonia, areflexia, dystonia and cognitive impairment\(^1\)\(^2\)\(^0\). Children with aNAD may develop optic atrophy\(^9\). Brain MRI usually have similar features observed in INAD: abnormal iron accumulation in globus pallidus, dentate nuclei and substantia nigra, and cerebellar atrophy\(^2\)\(^0\).

Adult-onset PLAN with dystonia and parkinsonism, described as PARK14, has onset in young adulthood. Clinical features include parkinsonism-dystonia syndrome with variable response to dopaminergic medications and neuropsychiatric symptoms\(^9\). Brain MRI may be normal or may disclose iron accumulation in globus pallidus, substantia nigra and striatum\(^2\)\(^1\).

There is no specific treatment for PLAN. Symptomatic treatment for spasticity, dystonia and parkinsonism should be tried\(^1\). A levodopa course for parkinsonism may improve symptoms\(^1\)\(^3\).

**Neuroferritinopathy**

Neuroferritinopathy is a rare autosomal dominant NBIA of adult-onset related to a mutation in the ferritin light chain gene \(FTL\) on chromosome 19q13.3\(^1\)\(^9\). The onset of symptoms is predominantly described in young adulthood or middle age\(^1\). The clinical manifestation includes psychiatric symptoms (psychosis, anxiety and depression), frontal lobe dysfunction, dystonia, choreoathetosis, rigidity and spasticity. Other abnormalities described in patients with neuroferritinopathy include lingual dyskinesia, blepharospasm, cerebellar symptoms,

---

**Figure 1.** Brain MRI of a patient with pantothenase kinase-associated neurodegeneration (PKAN). Axial FLAIR- (A) and GRE T2-weighted (B) MRI discloses ‘eye-of-the-tiger’ sign, defined as a medial area of hyperintense signal within an hypointense signal in globus pallidus bilaterally.

**Figure 2.** Patient with phospholipase A2 associated neurodegeneration (PLAN) due to \(PLA2G6\) mutations. Brain MRI shows marked hypointense signal with iron accumulation in globus pallidus.
parkinsonism and palatal tremor. Blood tests show low levels of serum ferritin, typically ≤20 μg/dl, which may reinforce the diagnosis. Brain MRI findings include iron accumulation in globus pallidus, caudate, substantia nigra, red nuclei and putamen. In late stages of the disease cystic necrosis in basal ganglia and globus pallidus may occur. Pathological studies have demonstrated ubiquitin and tau positive neuroaxonal spheroids and neurofilaments, and ferritin-positive inclusions in putamen and cerebellum. Treatment is symptomatic and supportive, and dystonia may benefit with botulinum toxin. No curative treatments are available.

Aceruloplasminemia

Aceruloplasminemia is an autosomal recessive disease caused by mutation in the ceruloplasmin gene. Ceruloplasmin is a copper-bound ferroxidase essential to normal iron metabolism, including cell iron efflux and oxidation of ferrous iron to ferric iron. When ceruloplasmin activity is severely decreased, iron overload occurs and tissue iron deposition and degeneration follows. Iron accumulates primarily in the brain, retina and pancreas, giving rise to the classical presentation of the disease, a triad consisting of neurological symptoms, retinal degeneration and diabetes mellitus. The prevalence of aceruloplasminemia is higher in Japan.

Symptoms onset in aceruloplasminemia usually occur in the fourth decade. Typically, the first manifestation of the disease is diabetes mellitus accompanied by microcytic anemia with low serum iron, elevated ferritin and hepatic iron deposition without fibrosis or cirrhosis. Retinal macular degeneration is usually asymptomatic. Neurological symptoms develop later in the disease, around the sixth decade of life. Movement disorders are the most common neurological features in aceruloplasminemia and include ataxia, cranio-facial dyskinesias (torticollis, blepharospasm, facial grimacing and tongue dystonia), parkinsonism and dysarthria. Dementia and other neuropsychiatric symptoms are frequent in aceruloplasminemia.

Diagnosis of aceruloplasminemia is based on the absence or very low serum ceruloplasmin. Brain MRI usually discloses severe iron accumulation in caudate, pallidus, putamen, dentate nuclei, red nuclei, substantial nigra, thalamus, inferior and superior colliculi and cortex (Figure 3). This widespread pattern of involvement helps distinguish aceruloplasminemia from other NBIA, in which iron deposition is either more limited (e.g. confined to the pallidus) or associated with other features (e.g. cavitation, cerebellar atrophy or thin corpus callosum). White matter T2 hyperintensities can also occur. Heterozygous cases can present with an incomplete clinical picture, generating further diagnostic difficulties. Genetic testing confirms the diagnosis.

A number of iron chelating agents have been tried with mixed results and data on efficacy is scarce. Deferasirox reduces hepatic but not brain iron overload. Sporadic reports have demonstrated that deferasirox and deferiprone may delay neurological symptoms.

Beta-propeller protein-associated neurodegeneration (BPAN)

BPAN is a X-linked dominant form of NBIA caused by mutations in WDR45 gene, a β-propeller scaffolding protein, associated with disruption of autophagosome maturation, accumulation of aberrant autophagic structures and damaged cellular components.

Clinically, BPAN is characterized by two phases of disease: an early neurological disorder with rapid progression and a static encephalopathy of childhood. The early onset phenotype includes neurological symptoms similar to Rett-like syndrome: epilepsy, sleep disorders and global developmental delay, followed by a rapid progressive onset of parkinsonism, dystonia, and dementia. The second form is a static encephalopathy of childhood with neurodegeneration in adulthood (SENDA syndrome), which typically presents with hyperintense signal of the substantia nigra with a central band of hypointense signal in brain MRI (Figure 4).
Neuropathological studies have disclosed large axonal spheroids, siderophages, reactive astrocytes, severe neuronal loss and abundant tau-positive neurofibrillary tangles, suggesting the occurrence of a tauopathy40,43.

Kufor-Rakeb syndrome – PARK 9

The mutation of the gene ATP13A2 (PARK9) results in a rare autosomal recessive form of juvenile parkinsonism, previously known as Kufor-Rakeb syndrome44. The first cases described presented early parkinsonism, pyramidal signs, upgaze palsy and mental retardation45. However, it is recognized that the wide-ranging abnormalities in the gene leads to loss of function mutations, which impact the pathophysiological function of ATP13A2 protein resulting in considerable clinical heterogeneity46. Moreover, the mutations in heterozygous state have been found in parkinsonian patients suggesting that heterozygous carriers may increase risk for development of the disease45.

The onset of Kufor-Rakeb syndrome is mostly before the age of 20, with variable disease progression. The clinical manifestations comprise levodopa-responsive parkinsonism, dystonia, pyramidal signs, facial-finger mini-myoclonus, supranuclear gaze palsy and cognitive impairment47. Brain MRI usually shows global atrophy. The disease is included in NBIA group since T2* weighted sequence discloses iron accumulation in basal ganglia in some patients48.

Mitochondrial membrane protein-associated neurodegeneration (MPAN)

MPAN is an autosomal recessive disease caused by mutations in C19orf12 gene. Pathological studies have demonstrated increased iron accumulation in the globus pallidus and substantia nigra, gliosis, neuronal loss, and eosinophilic spheroidal structures in the globus pallidus. The characteristic peripheral axonal spheroids of PLAN may be seen in some patients. MPAN is considered a synucleinopathy, with Lewy bodies and Lewy neurites in basal ganglia and neocortex19,49.

The disease may manifest from the first decade of life (3-16 years) to adulthood (until 30 years). The most common features are early lower limb spasticity with extensor plantar response, dysarthria, dystonia (involving hands and feet), optic atrophy, neuropsychiatric abnormalities and cognitive decline. The presentation in adults is more variable, with prominent neuropsychiatric symptoms, parkinsonism and gait disorders. Others clinical findings that support the diagnosis of MPAN are dysphagia, axonal motor neuropathy and bladder and/or

Figure 4. Brain MRI of a patient with beta-propeller protein-associated neurodegeneration (BPAN) or SENDA. There is a marked bilateral hypointense signal in substantia nigra observed in axial and coronal FLAIR (A and B), axial T2 (C) and axial SWI (D) sequences.
bowel dysfunction. The disease progression is slow and the lifespan is long in most of the cases\textsuperscript{19,49}.

The diagnosis of MPAN is made by detection of biallelic pathogenic variants in \textit{C19orf12} gene. Brain MRI shows iron accumulation in substantia nigra and globus pallidus on T2\textsuperscript{*} and GRE sequences, normally without the eye of the tiger sign, which is typically found in PKAN. Cortical and cerebellar atrophy may be seen in advanced disease\textsuperscript{19,49,50}. Similar to others NBIA, there is no curative treatment and the management of patients relies on rehabilitation and symptomatic medications: anti-spastic agents, anticholinergics, dopaminergic agents and botulinum toxin.

**Fatty acid hydroxylase-associated neurodegeneration (FAHN)**

FA2H mutations were previously known to cause leukodystrophy and a form of hereditary spastic paraplegia (HSP), which was classified as SPG35\textsuperscript{31,32,33}. FA2H produces 2-hydroxylated fatty acids for incorporation into 2-hydroxydihydroceramide and 2-hydroxyceramide. These ceramide species serve as precursors for the synthesis of galactosylceramides and sulfatides, essential lipid components of normal myelin\textsuperscript{34,55}. Phenotypically, affected patients demonstrated features similar to those observed in INAD\textsuperscript{55}. The clinical phenotype is characterized by childhood-onset spastic paraplegia, ataxia and dystonia. There are prominent ophthalmologic features such as acquired strabismus, nystagmus and optic atrophy. Intellect is usually spared in FAHN patients. Seizures may be present\textsuperscript{51}.

Brain MRI in FAHN usually shows bilateral globus pallidus T2 hypointense signal, characterizing iron accumulation, pontocerebellar atrophy and cortical atrophy (Figure 5). Confluent periventricular T2 white matter hyperintense signal were also observed along with thinning of the corpus callosum\textsuperscript{51,55}. It is a matter of discussion if FAHN should be included in one or more of the 3 following groups: NBIA, HSP or leukodystrophy.

![Image](image-url)

**Figure 5. Patient with fatty acid hydroxylase-associated neurodegeneration (FAHN).** Brain MRI shows bilateral globus pallidus hypointense signal, characterizing iron accumulation, and confluent periventricular white matter hyperintense signal.

**CoA synthase protein associated neurodegeneration (CoPAN)**

Coenzyme A synthesis (CoASY) is a cofactor in all living organisms and is involved in several enzymatic reactions. Patients with CoASY mutations present a clinical picture similar to those with PKAN. CoPAN phenotype is characterized by early-onset spastic-dystonic paraparesis with a later appearance of parkinsonian features, cognitive impairment and pronounced obsessive-compulsive disorder. The disease has a slow progression with loss of ambulation during adolescence and adulthood\textsuperscript{56}. Brain MRI usually shows bilateral “eye-of-the-tiger” sign. CT scan shows bilateral calcifications and corresponding to the central spot visible on MRI\textsuperscript{57}.

**Woodhouse–Sakati syndrome and SCPx deficiency**

Woodhouse–Sakati syndrome is a rare autosomal recessive disorder caused by a mutation in the \textit{C2orf37} gene, manifesting with hypogonadism, deafness, alopecia, diabetes mellitus and progressive dystonia, chorea, dysarthria and cognitive impairment. Brain MRI discloses iron accumulation in the substantia nigra and globus pallidus, and white matter lesions. However, some patients may have only subtle white matter abnormalities\textsuperscript{57,58}.

Finally, sterol carrier protein x (SCPx) deficiency has been associated with NBIA in a patient with adult-onset spino-cerebellar ataxia, slow ocular saccades, and deafness. 3T MRI brain revealed abnormal T2 signal and susceptibility-weighted sequences suggested increased mineral deposition in the basal ganglia. Potentially pathogenic mutations were identified in SCP2. SCPx is a peroxisomal enzyme with thiolase activity required for the breakdown of branched chain fatty acids and the pathogenic effects are likely to be mediated by the accumulation of branch chain fatty acids, as in other peroxisomal disorders. Patients with SCP2 mutation may have abnormal fatty-acid acyl-CoA metabolism, which has emerged as a common disease mechanism in NBIA. This suggests that the brain iron accumulation is secondary to an underlying metabolic defect, questioning the role of iron chelation as a treatment in all forms of NBIA\textsuperscript{59}.

**Diagnostic approach to neurodegeneration with brain iron accumulation**

To diagnose the NBIA subtype is a challenge. Careful attention to clinical phenotype and neuroimaging features is crucial. Family history in order to determine inheritance is relevant since mendelian inheritance forms may direct investigation to neuroferritinopathy. Neuroimaging features may disclose key findings for different NBIA subtypes (Table 2). Altogether, clinical features including non-neurological manifestation, associated movement disorders, age at onset, family history and detailed neuroimaging characteristics should guide to the genetic testing investigation (Figure 6).
Figure 6. A guidance with clinical and neuroimaging tips to better require specific genetic testing in NBIA patients.
