Abstract - This paper presents a methodology to simulate a small-scale fuel cell system for power generation using biomass gas as fuel. The methodology encompasses the thermodynamic and electrochemical aspects of a solid oxide fuel cell (SOFC), as well as solves the problem of chemical equilibrium in complex systems. In this case the complex system is the internal reforming of biomass gas to produce hydrogen. The fuel cell input variables are: operational voltage, cell power output, composition of the biomass gas reforming, thermodynamic efficiency, electrochemical efficiency, practical efficiency, the First and Second law efficiencies for the whole system. The chemical compositions, molar flows and temperatures are presented to each point of the system as well as the exergetic efficiency. For a molar water/carbon ratio of 2, the thermodynamic simulation of the biomass gas reforming indicates the maximum hydrogen production at a temperature of 1070 K, which can vary as a function of the biomass gas composition. The comparison with the efficiency of simple gas turbine cycle and regenerative gas turbine cycle shows the superiority of SOFC for the considered electrical power range.

Keywords: Fuel Cell; Hydrogen; Biomass Gas; Simulation.

INTRODUCTION

The demonstration of fuel cell power generation is occurring worldwide. In the short term, for some specific applications these systems can become competitive, such as distributed generation and backup systems. The quality of the energy produced and the security of supply are attractive parameters of fuel cell systems. In the same way, such systems are also a promising alternative where local resources are available or where the substitution of subsidized fuels is possible, as in several isolated Brazilian areas.

As electrochemical devices rather than thermal engines, fuel cell systems are not limited to the maximum thermal efficiency, namely the Carnot efficiency. The hydrogen conversion into electricity occurs in a controlled manner and with less irreversibilities than the combustion process. Besides, the exhaust gas of a fuel cell system operating with H2 is solely water vapor.
However, the use of fuel cells relies on hydrogen availability. This feedstock can be competitively produced through reforming of fuels, such as natural gas, ethanol, and syngas from biomass gasification. These last two fuels are promising hydrogen sources in Brazil due to the country’s high potential for biomass production.

The overall efficiency of hydrogen production is a function of the partial efficiencies associated with each process stage. The international experience demonstrates that there are fuel cell systems with higher overall efficiencies than conventional power plants, even in those cases in which reforming-based hydrogen is used, which reduces the fuel cell performance compared to using purified hydrogen. The attainment of higher overall efficiencies in such systems is an important step towards the commercial application of this technology.

This paper presents a methodology to simulate the thermodynamics of fuel cell systems. The first and second simulation steps comprise, respectively, the steam reforming of gasification-derived biomass gas and the power generation. The fuel cell considered here was the SOFC (solid oxide fuel cell) at the operating temperature of 1173 K.

Description of the Fuel Cell System

Figure 1 shows the SOFC system. The gas temperature at point 1 is 1173 K and the gas was formed in a steam gasification reactor (fluidized bed) with indirect heating (IG). The point 14 shows the steam flow needed for the reforming process. Actually the gas leaves the gasifier at high temperature and in wet phase, but in this paper the dry gas and steam flow were considered separately.

![Figure 1: SOFC system](image)

The biomass gas (point 1) passes through the compressor (GC) and enters into the internal reforming reactor; then the reformed syngas (point 3) is directed to the electrochemical reaction at the SOFC. The anode exhaust gas (point 4) is used at the combustion chamber and the combustion gas (point 5) heats the air flow (point 9 – point 10) through a heat exchanger (HT1). The cathode exhaust gas is used to pre-heat the air (point 8) through a heat exchanger (HT2). The flow 13 is the air supply for combustion.

THEORETICAL ANALYSIS OF FUEL CELLS SYSTEMS

Thermodynamics of the Fuel Cell

The fuel cell is an electrochemical device that converts the Gibbs’ free energy of a fuel directly into electricity. According to Kordesch and Simader (1996), the thermodynamics of the fuel cell is represented by the equations below. Global reaction of hydrogen with oxygen from air:

\[
\text{H}_2(\text{g}) + \frac{1}{2}\text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{l})
\]  

(1)

In usual reactors the chemical reactions undergo irreversible processes in which the sole work done is the change in enthalpy (\(\Delta H\)). It occurs by isothermal, isobaric heat transfer with the surroundings. The change in enthalpy is expressed by the equation,

\[
dH = dG + TdS
\]  

(2)

If the reactions are irreversible, the terms \(dG\) and \(TdS\) will manifest as heat, although several electrochemical reactions may occur reversibly within a fuel cell. In this case, \(dG\) occurs as electrical work and therefore constitutes the maximum value of the term \(dH\) that can be converted into electricity, as shown by Eq.(3) as follows:

\[
\delta W_\text{el} = dH - TdS = dG
\]  

(3)

Therefore, the possible maximum electrical work is the change in the Gibbs’ free energy. Considering the reactants and the products at the standard reference state (\(T = 298.15\) K, \(P = 101.3\) kPa) and integrating Eq.(3), the result is Eq.(4)

\[
W_\text{el}^0 = \Delta G^0
\]  

(4)

in which the ratio between \(\Delta G\) and \(\Delta H\) is called the maximum theoretical efficiency or the thermodynamic efficiency of a fuel cell (\(\eta_{th}\)):

\[
\eta_{th} = \frac{\Delta G}{\Delta H}
\]  

(5)
In the reaction described by Eq.(1), two electrons are transferred to a circuit external to the fuel cell. For each mol of H₂ involved in the reaction, 2N electrons are transferred, where N is the Avogadro’s number. If \( e \) is the charge of a single electron, then the charge flow will be:

\[
2Ne = 2F
\]  

(6)

Hence the total charge transferred can be expressed as a function of the number of moles of H₂, or 2nH₂ F. During the operation of the fuel cell, a difference of potential \( E \) appears between its electrodes, which, multiplied by the amount of charge, results in the work of the fuel cell:

\[
W_{el} = 2n_{H_2}F \Delta E
\]  

(7)

Considering \( 2n_{H_2}F = C \) and substituting Eq.(4) into Eq.(7), the electrical work of the fuel cell in the standard reference state is

\[
\Delta G^0 = CE^0
\]  

(8)

where \( E^0 \) in the Eq.(8) is the reversible potential or the maximum operational voltage of a fuel cell under the standard reference conditions. Based on Eq.(1), it results in 1.229 V. However, the actual cell potential is lower due to irreversible losses. Multiple phenomena contribute to these irreversible losses or overpotentials, which originate primarily from three sources: activation polarization, ohmic polarization, and concentration polarization. These losses result in a cell voltage that is lower than its ideal potential. Such concepts are not discussed here.

A parameter that can be used to quantify the effects of overpotentials is the electrochemical efficiency, which is defined as the ratio between the actual operational voltage and the reversible potential,

\[
\eta_{elq} = \frac{W_{el}}{\Delta G^0} = \frac{W_{el}}{W_{el0}}
\]  

(9)

The electrochemical efficiency is a measure of the fuel cell quality, though not taking into consideration the lifetime, costs and other parameters. In order to compare fuel cells with different characteristics, in which the same reaction occurs, differences in the electrochemical efficiencies are verified (Kordesch and Simader, 1996).

The practical efficiency of a fuel cell is defined as the ratio between the actual work and the enthalpy of the fuel cell or as (Matelli and Bazzo, 2005) the product of the thermodynamic and the electrochemical efficiencies,

\[
\eta_{prl} = \frac{W_{el}}{\Delta H} = \eta_{th} \eta_{elq}
\]  

(10)

For a fuel cell system operating with hydrogen derived from the reformed producer gas from biomass gasification, the overall efficiency is associated with the total power output and the gas lower heating value (LHV). It is named the first law efficiency of the SOFC/ gasification system:

\[
\eta_l = \frac{W_{el}}{n_{GGAS} \text{LHV}_{GGAS}}
\]  

(11)

### Gasification-Derived Biomass Gas Reforming

The producer gas from biomass gasification has a mole fraction of hydrogen that can be maximized by the reforming of the mole fractions of methane (CH₄), hydrocarbons (CxHy), and carbon monoxide (CO). The simulation of the steam reforming considered a pressure of \( P = 101.3 \) kPa and a molar water/carbon ratio of 2. Table 1 illustrates the mole fractions of gas mixture (dry phase) produced by the indirect circulating fluidized bed (with steam) gasification processes reported by Bain (2004).

Table 1: Gasification gas composition

The steam reforming process is defined as a thermo-chemical and catalytic conversion of a liquid, solid or gaseous fuel into a hydrogen-rich mixture. It is a process in which high temperature steam (973 - 1273 K) is used to produce hydrogen from a methane source such as, for example, natural gas or biomass gas. In steam methane reforming, methane reacts with steam in the presence of a catalyst (nickel-
alumina) to produce hydrogen, carbon monoxide, and a relatively small amount of carbon dioxide (Silva, 1991).

The best-known reforming methods are: steam reforming, partial oxidation, and auto-thermal reforming (Ahmed and Krumpelt, 2001). In this work, steam reforming was considered. The global reforming reaction of the gasification-derived biomass gas is described by Eq. (12)

$$\text{CH}_4 + \text{C}_2\text{H}_4 + \text{CO} + \text{H}_2\text{O} \rightarrow \text{H}_2 + \text{CO} + \text{CO}_2 + \text{H}_2\text{O}$$ (12)

For these biomass gas processing reactions, there are many possible products, it being important to estimate the composition of the syngas at the outlet of the reforming bed according to the thermodynamic conditions of the process being carried out. This estimate, considering the pre-design of the reforming and hydrogen purification systems, makes possible the assessment of the catalysts applied in prototypes (Marin Neto et al., 2004). Such assessment consists of verifying the selectivity achieved for each one of the chemical species considered and the contribution of the catalysts in shifting the chemical equilibrium towards higher hydrogen concentration in the syngas. In the case of the SOFC system simulation, the amount of hydrogen available for electricity generation can be obtained.

These complex systems, which consist of several chemical species in determined thermodynamic states, can be solved through the quantification of the chemical equilibrium (Fishtik et al., 2000). Such complex system can be described by the following equations.

$$\frac{\partial G}{\partial n_i} = \sum_{i=1}^{N} \lambda_k n_i b_{i,k} - B_k$$ (13)

Eq.(13) represents the minimization of the Gibbs’ free energy at the equilibrium state of a system under determined temperature and pressure conditions. According to the inlet conditions of the system, the mass balance can be evaluated by Eq.(14),

$$\sum_{i=1}^{N} n_i b_{i,k} = B_k$$ (14)

Where $n_i$ denotes the number of moles of the substance i; $b$ is the number of atoms of the chemical element k in the substance i and B represents the total number of atoms of the chemical element k in the system. The problem resides in solving a set of intrinsically dependent equations with the aim of achieving the minimum energy requirement for gas reforming for a given boundary condition.

The appropriate mathematical tool to solve such problem is the Lagrange multipliers. In this case, the fractions responsible for the mass balance in each of the constituent equations of the systems are multiplied by the scalars (Lagrange multipliers). Hence, Eq.(14) is re-written as:

$$\sum_{i=1}^{N} \lambda_k \left( \sum_{i=1}^{N} n_i b_{i,k} - B_k \right) = 0$$ (15)

where $\lambda_k$ is the Lagrange multiplier. A function F is defined in a way that:

$$F = G + \sum_{i=1}^{N} \lambda_k \left( \sum_{i=1}^{N} n_i b_{i,k} - B_k \right)$$ (16)

It follows that:

$$\left( \frac{\partial F}{\partial n_i} \right)_{T,P} = \left( \frac{\partial G}{\partial n_i} \right)_{T,P} + \sum_{k} \lambda_k a_{i,k} = 0$$ (17)

where a is the activity, and the first term on the right after the equal sign of Eq.(17) is the definition of the chemical potential, $\mu_i$, which can also be written by Eq.(18),

$$\mu_i = G_{i}^0 + RT \ln \frac{\hat{\phi}_i P}{P_0}$$ (18)

where $\hat{\phi}_i$ is the fugacity coefficient of species i in solution under ideal gas conditions; $G_{i}^0$ is the molar partial Gibbs energy under standard conditions. Combining Eqs. (17) and (18) yields,

$$G_{i}^0 + RT \ln \frac{\hat{\phi}_i P}{P_0} + \sum_{k} \lambda_k a_{i,k} = 0$$ (19)

These equations, together with the mass balance equations, define the system of equations that describes the chemical equilibrium problem. In this work, the EES® (Engineering Equation Solver) (Klein and Alvarado, 2003) is used for simulating the reforming of the gasification-derived biomass gas.
System Performance Analysis

The methodology used for the system performance analysis was the energy and exergy balances. The power output considered in this work was stacks of 250 kWel, where the assumed operational voltage for each unit cell, \( V_{\text{op}} \), was 0.67 V, in accordance with the literature.

Firstly, the problem consists in determining the consumption of hydrogen and biomass gas of the SOFC stack, which can undergo gas internal reforming. Secondly, this problem is combined with the chemical equilibrium solution of the biomass gas reforming described before.

Hence, the hydrogen consumption of the electrochemical reaction can be determined by rewriting Eq.(7) as,

\[
\dot{n}_{\text{H}_2} = \frac{\dot{W}_{\text{el}}}{2F_{\text{op}}}
\]

in which \( \dot{n}_{\text{H}_2} \) is the hydrogen molar flow rate per unit cell. Nevertheless, not all hydrogen supplied to the cell reacts electrochemically, the fuel utilization factor being defined as the ratio between the hydrogen consumed and the hydrogen supplied to the anode, as given by Eq.(21),

\[
\Phi = \frac{\dot{n}_{\text{H}_2,\text{rect}}}{\dot{n}_{\text{H}_2,\text{spl}}}
\]

A good estimate for \( \Phi \) according Larminie and Dicks (2003) is 0.9, which was considered in this paper.

For a stack with a number \( N \) of unit cells, the hydrogen molar flow rate is given by Eq.(22),

\[
\dot{n}_{\text{H}_2,\text{stk}} = N\dot{n}_{\text{H}_2,\text{spl}}
\]

The biomass gas consumption of the stack is determined considering the mole fraction of the hydrogen within the anode gas calculated from the chemical equilibrium problem of the steam reforming; thus, Eq.(23) is applied,

\[
\dot{n}_{\text{GGAS,stk}} = \frac{\dot{n}_{\text{H}_2,\text{stk}}}{Y_{\text{H}_2}}
\]

Equations (24) and (25) represent the enthalpy and entropy calculations for an ideal gas mixture.

\[
\bar{h}_i = \sum_{i=1}^{N} y_i \left( \bar{h}^0_i + \int_{T_0}^{T} \frac{\bar{c}_P}{T} dT \right)
\]

\[
\bar{s}_i = \sum_{i=1}^{N} y_i \left( \bar{s}^0_i + \int_{T_0}^{T} \frac{\bar{c}_P}{T} dT - R \ln(y_i) \right)
\]

The energy balance of the fuel cell stack is determined by Eq.(26), where part of the heat produced by the stack is used for the reforming.

\[
\dot{Q}_{\text{ref}} - \dot{Q}_{\text{stk}} + \dot{W}_{\text{stk}} - \dot{W}_{\text{aux}} = \sum_{i=1}^{N} \dot{n}_{\text{out}} \dot{h}_{\text{out}} - \sum_{i=1}^{N} \dot{n}_{\text{in}} \dot{h}_{\text{in}}
\]

The thermodynamic, electrochemical and practical efficiencies are calculated considering the changes of enthalpy, entropy and Gibbs’ free energy according to Eqs.(27), (28) and (29),

\[
\Delta H = n_{\text{H}_2\text{O}} \bar{h}_{\text{H}_2\text{O}} + n_{\text{CO}_2} \bar{h}_{\text{CO}_2} - n_{\text{O}_2} \bar{h}_{\text{O}_2}
\]

\[
\Delta S = n_{\text{H}_2\text{O}} \bar{S}_{\text{H}_2\text{O}} + n_{\text{CO}_2} \bar{S}_{\text{CO}_2} - n_{\text{O}_2} \bar{S}_{\text{O}_2}
\]

\[
\Delta G = \Delta H - T\Delta S
\]

The mass, energy and exergy balances within the combustion chamber and heat exchangers are represented by Eqs. (30) to (32).

\[
\sum \dot{m}_{\text{in}} = \sum \dot{m}_{\text{out}}
\]

\[
\dot{Q} = \sum \dot{n}_{\text{out}} \bar{h}_{\text{out}} - \dot{n}_{\text{in}} \bar{h}_{\text{in}}
\]

\[
\dot{E}_{\text{x}} \dot{Q} - \dot{E}_i = \dot{n}_{\text{out}} (\bar{e}_{\text{x}} \text{out}) - \dot{n}_{\text{in}} (\bar{e}_{\text{x}} \text{in})
\]

The definitions of specific physical and chemical exergy [8] are represented by Eqs.(33) and (34), and Eq.(35) for heat transfer.

\[
\bar{e}_{\text{x}} \text{ph} = (\bar{h} - \bar{h}_0) - T_0 (\bar{S} - \bar{S}_0)
\]

\[
\bar{e}_{\text{x}} \text{ch} = \sum_{i=1}^{N} y_i \bar{e}_{\text{x},i} + \bar{R} T_0 \sum_{i=1}^{N} y_i \ln y_i
\]

\[
\dot{E}_{\text{x}} \dot{Q} = Q \left[ 1 - \frac{T_0}{T} \right]
\]
The total specific exergy is:

$$\bar{e}_x = \bar{e}_{x_{ch}} + \bar{e}_{x_{ph}}$$  \hspace{1cm} (36)

The standard reference conditions (298.15 K and 101.3 kPa) in which physical and chemical exergies are defined were considered to be those proposed by Szargut et al. (1988), whose standard chemical exergies are presented in Table 2.

The exergy balance leads to the concept of rational efficiency, defined as the ratio between the total outlet exergy and the total inlet exergy, according to Eq. (37),

$$\psi = \frac{1}{\sum \frac{\dot{E}_{x_{in}}}{\dot{E}_{x_{in}}}} - \sum \frac{i}{\dot{E}_{x_{in}}}$$  \hspace{1cm} (37)

For the combustion chamber, the rational efficiency is:

$$\psi = \frac{\dot{E}_{x_{4}} + \dot{E}_{x_{13}}}{\dot{E}_{x_{5}} + \dot{E}_{Q}}$$  \hspace{1cm} (38)

The electrical efficiency of the system is calculated by the ratio between the useful power and the chemical exergy of the biomass gas,

$$\eta_{el} = \frac{W_{net}}{\dot{E}_{x_{ch,GGAS}}}$$  \hspace{1cm} (39)

where

$$W_{net} = W_{el} - W_{aux}$$  \hspace{1cm} (40)

The exergetic efficiency of the system is:

$$\eta_{II} = \frac{W_{net}}{\dot{E}_{x_{GGAS}} + \dot{E}_{x_{H2O}}}$$  \hspace{1cm} (41)

RESULTS

According to the methodology presented in section 3.2, in which the mass balance is weighted by the energy minimization of the system and, then, the amount of each chemical species can be quantified, the solution can be presented as a continuum according to Fig.2.

Fig. 2 shows that the maximum biomass gas conversion occurs at 1070 K, where the hydrogen production is the highest. Such maximum hydrogen molar fraction temperature is quite close to the SOFC operational temperature (1173 K), hence this type of fuel cell has a high potential to be integrated to a biomass gasification reactor. However, the great disadvantage of the biomass gas is the amount of impurities produced by the gasification process which certainly constitutes a barrier to this integration. Tar is the main contaminant, which can obstruct and deactivate the reactive surfaces of the fuel cell. The existence of a system for tar hot pre-cleaning would be ideal so that the gas high temperature could be used at least partly in the reforming process.

Tables 3 and 4 present the simulation results referred to the points of the system at Fig.1.

Comparing the results in Table 5 to the simulation performed by Matelli and Bazzo (2005), the inferiority of the SOFC system/ biomass gas can be observed. Those authors simulated a SOFC system/ natural gas, where the efficiencies \( \eta_{\text{th}} \), \( \eta_{\text{elq}} \), \( \eta_{\text{prt}} \) and \( \eta_{\text{II}} \), were, respectively, 73.5\%, 70.7\%, 52.0\% and 43.4\%. This superiority is due to the higher potential of producing hydrogen from natural gas reforming compared to biomass gas reforming, in accordance to the higher hydrogen mole fraction derived from natural gas reforming. The lower hydrogen production potential derived from biomass gas results in a higher system entropy generation. Table 6 presents the rational efficiencies of some components of the system. While the SOFC rational efficiency reaches 71.7\%, the simulation performed by Matelli and Bazzo (2005) yielded a value of 89\%. The biomass gas advantage over natural gas is that it is renewable.

Depending on the gasification process and its agent (air, oxygen, steam), the biomass gas can present different compositions, which suggests different hydrogen mole fractions within the reformed gas. In Fig. 3, for instance, the reformed gas mole fractions are presented, obtained from the thermodynamic simulation of the steam reforming of the producer gas derived from the air gasification reactor (fluidized bed) with direct heating. The composition of this biomass gas according to Bain (2004) is $10\%$mol.mol$^{-1}\text{H}_2$, $12.7\%$mol.mol$^{-1}\text{CO}$, $16.7\%$mol.mol$^{-1}\text{CO}_2$, $56.4\%$mol.mol$^{-1}\text{N}_2$, $3.7\%$mol.mol$^{-1}\text{CH}_4$, $0.5\%$mol.mol$^{-1}\text{C}_2\text{H}_4$. Such a process produces low energy-content gases, with lower methane mole fraction and, thus, with less potential to produce hydrogen. It is also noted that the maximum hydrogen mole fraction is reached at a temperature of 900 K, different from the 1070 K presented in Fig. 2.

As a consequence, the efficiency of the SOFC system may vary as a function of the chemical species mole fractions present in the gas mixture. Fig. 4 illustrates the electrical efficiency variation of a SOFC system as a function of the hydrogen mole fraction of the biomass reformed gas. Those mole fractions were obtained from chemical equilibrium equations, considering different compositions of gases produced by different biomass gasification processes.

The lowest electrical efficiency of the SOFC system (Fig. 4) corresponds to the gas produced by an air gasification reactor (fluidized bed) with direct heating and, on the other hand, the highest efficiency occurs for the gas produced by a steam gasification reactor (fluidized bed) with indirect heating. The deviation of the points from the adjusted curve is due to the efficiency dependence on the mole fractions of the other species, such as carbon monoxide.

Finally, it is worth comparing the electrical efficiency of the SOFC system to conventional heat engines. According to international experience, fuel cell electrical efficiency is superior to that of heat engines, although such superiority is more significant when pure hydrogen is used. The reforming process to produce hydrogen results in irreversibilities that may decrease the advantage of fuel cells over heat engines.

Furthermore, this work compared the electrical efficiency of the SOFC system to that of gas turbines. In order to do so, gas turbine thermodynamics from Cohen et al. (1996), Kolanowski (2004), and performance information of some commercial simple and regenerative cycle units of gas turbines was needed. The origins of the gas turbine performance data are given in the references.
In Fig. 5 the electrical efficiencies are presented for the SOFC system and gas turbines with electrical power output ranging from 500 kW to 30,000 kW. The gas turbine electrical efficiencies were calculated through the ratio between the net electric power output and the chemical exergy of the biomass gas. The net electric power is obtained by deducting the power used to compress the gas, since the biomass gasification operates at atmospheric pressure.

Fig. 5 shows the SOFC electrical efficiency superiority over the whole electrical power range, although this advantage decreases as the power output rises due to the increase of the electrical efficiency of the simple cycle gas turbine. For the power output of 500 kW, the SOFC efficiency is 17% superior, but for 30,000 kW the efficiency is only 1% higher.

Fig. 6 presents the electrical efficiencies of the SOFC system and regenerative cycle gas turbines with electrical power output ranging from 30 kW (microturbines) to 4,500 kW. Although a regenerative cycle is apparently great in practice, it is only good for low compression ratio, so it is applicable in small gas turbines.

In this case, the SOFC system is still superior over all of the electrical power range. However, the SOFC system superiority is lower: 14% for 30 kW and 2% for 4,500 kW.

CONCLUSION

The thermodynamic modeling of biomass gas steam reforming (for a water / carbon mole ratio of 2) showed that the maximum hydrogen production for a pressure of 101.3 kPa depends on the biomass gas composition. For indirect heating steam gasification, the maximum hydrogen mole fraction in reforming gas \( y_{\text{H}_2} \) is 0.5 mol.mol\(^{-1}\) at a temperature of 1070 K, while for the direct heating air gasification the maximum \( y_{\text{H}_2} \) is 0.25 mol.mol\(^{-1}\) and occurs at 900 K. The \( y_{\text{H}_2} \) influences the electrical efficiency of a SOFC system; for \( y_{\text{H}_2} \) of 0.5 mol.mol\(^{-1}\) the electrical efficiency is 35% while for \( y_{\text{H}_2} \) of 0.2 mol.mol\(^{-1}\) the electrical efficiency is 30%. This result indicates a higher quality of the biomass gas from indirect steam gasification for application in a SOFC. In terms of the fuel quality, the integration of a SOFC with indirect steam gasification is more advantageous than its integration with direct air gasification.

The comparison of the electrical efficiency of a SOFC system with simple cycle gas turbine systems showed that the fuel cell efficiency can be significantly higher up to 5,000 kW, being approximately 10% more power-efficient. For this small-scale power, however, it is often more advantageous to make use of regenerative cycle gas turbines due to the lower compression ratio; in this case the difference in efficiency decreases to 5%, still in favor of the SOFC to a power of approximately 1,000 kW. Therefore, from the viewpoint of electrical efficiency, it is concluded that the SOFC is more interesting for distributed generation of electricity in a small scale system up to 1,000 kW.
