Abstract: The relative condition factors (Kn) of the fishes Astyanax paranae, Phalloceros harpagos and Poecilia reticulata were used as a means of assessing the influence of environmental conditions on the well-being of sub-populations of these species, with the eventual aim of using them as bioindicators of disturbance in tributary streams of the Monjolinho River, in São Carlos - SP. The power-law curve generated by the length-weight relationship indicated a positive allometric growth for the three species studied. Overall, the canonical correspondence analysis (CCA) positively correlated average Kn of A. paranae with well oxygenated and oligotrophic environments, typical of conserved areas or near the natural state. For the average value of Kn obtained for Phalloceros harpagos species, there was no significant difference between natural and disturbed areas. However, the CCA positively correlated the mean Kn of the species P. reticulata from similar environments with higher trophic level, suggesting that this species is indicative of disturbance.

Keywords: Biomonitoring, condition factor, length-weight relationship, degradation, bioindicators.

Resumo: Os fatores de condição relativo (Kn) de Astyanax paranae, Phalloceros harpagos e Poecilia reticulata foram utilizados como ferramenta para avaliar a influência da qualidade ambiental sobre o bem estar de sub-populações destas espécies, visando utilizá-las como bioindicadoras de distúrbios em córregos afluentes do rio Monjolinho, no município de São Carlos – SP. A curva potencial gerada pela relação peso-comprimento indicou um crescimento do tipo alométrico positivo para as três espécies estudadas. No geral, a análise de correspondência canônica (CCA) correlacionou positivamente o Kn médio da espécie A. paranae com ambientes bem oxigenados e oligotróficos, característicos de áreas preservadas ou próximas do estado natural. Para o valor médio do Kn obtido para a espécie Phalloceros harpagos, não ocorreram diferenças significativas entre áreas naturais e perturbadas. Entretanto, a CCA correlacionou positivamente o Kn médio da espécie Poecilia reticulata a ambientes impactados, com maior grau de trofia, o que sugere que o fator de condição relativo desta espécie pode ser utilizado como indicador de distúrbios, neste caso, ocasionado pela poluição orgânica.

Palavras-chave: Biomonitoramento, Fator de condição, relação peso-comprimento, degradação, bioindicadores.

Introduction

Natural ecosystems have suffered heavily over the last years from the impact of the combined effects of urbanization and other anthropogenic activities resulting from population growth. Many aquatic environments, such as rivers, lakes and reservoirs, which provide essential services to humanity, have undergone a number of changes due to human interference (König et al., 2008). In this context, aquatic communities are constantly exposed to pollution by the large number of compounds released into water bodies from various emission sources, including industrial effluent discharge, domestic sewage, agricultural waste and others (Rashed, 2001). Thereby, the environmental quality or degradation level of...
these ecosystems may be reflected by their biological communities, which respond differently to the effects of the disturbing agents, providing an indicator to assess the effects of these disorders (Barbour et al., 1999).

The organisms most frequently used in the assessment of the impacts on aquatic ecosystems are the benthic macroinvertebrates, fish and periphyton (Goulart & Callisto, 2003). In ichthyofauna studies, for instance, the parameters usually analyzed in the study of populations are the size and weight of the organisms. The length-weight relationship of fish is an important tool to distinguish aspects of their biology, physiology and ecology, and combined with other quantitative features, such as growth, recruitment and mortality, it provides valuable information about the species structure in an environment (Lizama & Ambro’sio, 1999).

Using the relationship between body weight and length, it is possible to derive a parameter that is a measure of wellness, providing information about how the animal takes advantage of the available resources. This parameter, known as the relative condition factor ($K_n$), is an important and powerful tool to demonstrate changes in the condition of fish over a certain period of time and can be used to indicate nutritional status, environmental changes, the reproductive period, the dietary changes period, the fat accumulation (Le Cren, 1951; Gomiero & Braga, 2003) and parasite infections (Lemos et al., 2007), making it possible to compare populations that are subjected to different climate conditions, water temperature, salinity and density, food availability and other conditions (Lizama & Ambro’sio, 2002; Rocha et al., 2005; Rêgo et al., 2008). Under normal conditions, the theoretically expected value of $K_n$ is 1, whereas any event that interferes with the health or welfare of the fish can produce variations in this value.

The improper use of land and natural resources, resulting from urban development without proper planning and agricultural activities in the catchment area of the Monjolinho River have caused large disturbances in the basin, especially in the area of headwaters in the city of São Carlos during the last few decades (Sé, 1992). The accelerated development occurring in areas where these headwaters are located interferes directly with the stability of aquatic ecosystems and, therefore, affects the water quality and aquatic biota across the whole river basin.

The aim of this study was to assess the conditions in the upper portion of the Monjolinho River catchment area. The study area is mapped in Figure 1, with stream names and sampling sites.

A brief description of each site follows:

- **Espraiado 1 (21°58'17.5" S; 47°52'18" W)**: Stream stretch in an area of dense and structured native vegetation, closed canopy, legally defined as a preserved area; a reference site for this study.
- **Espraiado 2 (21° 58' 52" S; 47°52'26" W)**: Stream stretch in an area with preserved riparian vegetation near a canalized portion. Both stretches (Espraiado 1 and 2) are located on Federal University of São Carlos land, enclosed in an area covered by cerrado sensu stricto and replanted Eucalyptus sp. forest.
- **Belvedere (21°59'54.3" S; 47°52'13.9" W)**: stretch located in an area with a small fragment of riparian vegetation, but with signs of burning and household waste, as well as earthworks that indicate the expansion of the Belvedere Park neighborhood. The stream is located in an urban development.
- **Ponte de Tábuas 1 (22°00'32.1"S; 47°51'38.8"W)**: stretch located in an urban area, near the Sábará Park condominium, with fragments of riparian vegetation and domestic waste collected along the stretch.
- **Ponte de Tábuas 2 (21°59'35.1" S; 47°51'43.2"W)**: stretch located in an urban area; Jardim Venezuela and Jardim Munique neighborhoods close to it, without riparian vegetation, with pipe for sewage discharge and grazing animals nearby.
- **Canhím stream (21°59'21.4"S; 47°51'14.2"W)**: stretch located inside Coqueiros Farm, with riparian vegetation and without evidence of household wastes.
- **São Rafael (22°00'52"S; 47°51'9.4"W)**: stretch located close to Jardim Tangará and São Rafael residential neighborhoods and with evidence of disturbance.
- **Douradinho (22°00'37"S; 47°50'28.3"W)**: stretch located inside Santa Joana Farm, characterized by a large forest fragment.

To analyze the sampling stretches, we used the Habitat Diversity Rapid Assessment Protocol described by Callisto et al. (2002), which assesses a set of variables and indicates the degree of conservation of the habitat as: natural (up 60 points), altered (41-60 points) or impacted (0-40 points).

Sampling was conducted in the months of July and August 2013: a metal wire sieve mesh (diameter = 0.75 m, mesh = 3 mm) and a net (0.50 m in diameter) were used to catch the fish fauna, with a sampling effort of one hour in each stretch (approximately 50 meters long). The specimens were fixed in 10% formalin and preserved in 70% alcohol for later identification and biometrics analysis. For taxonomic identification, the specialized bibliography, keys and descriptions available in the literature were used (Britski, 1972 Britski et al., 1999, modified by Casatti et al., 2001; Castro et al., 2004; Oliveira, 2006; Grace & Pavanelli, 2007; Lucinda, 2008), as well as the help of ichthyologists. Species with greater occurrence constancy were selected, according to the criteria of Dajoz (1983), as well as those with higher relative abundance at the collection sites, and the species that were present in the habitats of lowest and highest degradation were taken as references.

For each selected taxon, measurements of standard length (Ls) and fresh weight (Wo) were taken with digital calipers (King Tools) and a precision balance (Marte AS 2000c). These
data were used to fit an overall weight-length curve for each species, by adjusting a and b, the equation \( W = a \cdot L^b \) (Le Cren, 1951). With the estimated values of coefficients \( a \) and \( b \), the theoretical expected weights (\( We \)) for the respective values of standard length (\( Ls \)) were calculated. The values of the relative condition factor (\( Kn \)) calculated by the equation \( Kn = \frac{Wo}{We} \) for individuals sampled in each environment, and the \( Kn \) data sets for each species and their habitats were compared by the nonparametric Kruskal-Wallis test (complemented by Dunn’s test) at a significance level of 5%. Finally, each mean \( Kn \) was compared with the hypothetical average (\( Kn = 1 \)) by student’s \( t \)-test (Zar, 2010).

The physical and chemical data: pH, electrical conductivity, dissolved oxygen concentration and water temperature, were measured “in situ” with a HORIBA U-10 multiprobe, alongside the water sampling. The inorganic nutrients analyzed were: total phosphorus and nitrogen (Valderrama, 1981), nitrite (Bendchreider & Robinson, 1952, cited by Golterman et al., 1978), nitrate (Mackereth et al. 1978), ammonium (Koroleff 1976, cited by Mackereth et al. 1978) and dissolved total phosphate, organic phosphate and inorganic phosphate (Strickland & Parsons, 1960). Once the nutrient concentrations were established, the trophic state index (TSI) of Carlson (1977) modified by Lamparelli (2004) was calculated, using the total phosphorus concentration.

Canonical correspondence analysis (CCA), followed by a Monte Carlo test, with 999 random permutations, was used to test the existence of significant associations between environmental variables and the relative condition factor of each species, using the program CANOCO 3:12 (Šmilauer & Ter Braak, 2002).

Results

Fishes belonging to eight species, totaling 616 specimens, were collected in the sampled streams, of which Astyanax paranae (Eigenmann, 1914), Phalloceros harpagos (Lucinda, 2008) and Poecilia reticulata (Peters, 1859) were more numerous, both in occurrence (O) and relative abundance (A), than others: Hypostomus ancistroides (Ihering, 1911), Geophagus brasiliensis (Quoy & Gaimard, 1824), Rhamdia quelen (Quoy & Gaimard, 1824), Gymnotus carapo (Linnaeus, 1758) and Hypessobrycon anisitsi (Eigenmann, 1907) Table 1. Therefore, the first three were selected for the length-weight relationship and relative condition factor.

The score obtained for the Rapid Assessment Protocol, trophic state index (TSI) and physical and chemical variables are presented in table 2. The highest values for the physical and chemical variables, with the exception of dissolved oxygen, pH and temperature, were recorded in Belvedere stream. The lowest dissolved oxygen concentration was found in this stream too.

The Habitat Diversity Rapid Assessment Protocol classified as natural habitats (N) the Espraiado stream (E1 and E2), as altered streams (A) the Douradinho (D), Canchim (C), Ponte...

higher than 1, suggesting significantly more suitable environmental conditions for this fish than those in sites PT1 and PT2.

In contrast, Phalloceros harpagos individuals collected in Douradinho stream were in poor body condition, shown by the low average value of Kn (p<0.05) relative to the other streams and the standard Kn (Kn = 1).

The specimens of Poecilia reticulata showed a higher Kn value in Belvedere stream than in all the other streams where this species was recorded. Besides being the highest value among all the streams, the average Kn of this species in this stream was significantly higher than the standard value (Kn = 1) (Figure 3).

In the canonical correspondence analysis (CCA), the first two axes explained 98.5% of the total variability of the data (Figure 4). In general terms, the Belvedere stream (Bvd) was associated with higher nutrient concentrations, environmental disturbance, lower dissolved oxygen and higher abundance of Poecilia reticulata individuals. The species Astyanax paranae was correlated with natural habitat streams, with low nutrient concentrations and higher dissolved oxygen concentrations. In turn, Phalloceros harpagos individuals were associated with altered conditions, as in:

* DIN – Dissolved inorganic Nitrogen
Canchim (Cch), Ponte de Tábuas (PT1 and PT2) and São Rafael (SR), but not Douradinho stream. The Monte Carlo test showed that the differences in dissolved oxygen, nitrite and total phosphorus concentrations were significant (p < 0.05).

Discussion

The physical and chemical analysis, the Habitat Rapid Assessment Protocol of habitats and the trophic state index indicated a range of sites, from very clean to very impacted.

Figure 2. Length-weight relationship of the fish (A) Astyanax paranae, (B) Phalloceros harpagos and (C) Poecilia reticulata in the tributary streams of the upper Monjolinho river streams in São Carlos – SP.
Being located in conservation areas, with well structured vegetation and far from pollutant emission sources, Espraiado stream, 1 and 2, have a good environmental quality, with nutrient concentrations below the regional limits for natural systems, according to those described by Tundisi & Matsumura-Tundisi (2008). The Habitat Rapid Assessment Protocol and trophic state index corroborated the improved environmental quality of these stretches, classifying them as natural and oligotrophic environments, respectively. However, these instruments characterized the Canchim, Douradinho, Ponte de Tábuas 1 and 2 and São Rafael streams as mesotrophic and altered. In all streams except for Espraiado and Canchim streams, the dissolved inorganic nitrogen concentrations (ammonium, nitrite and nitrate) were higher than those found in natural habitats with low human intervention (around 0.12 mg.L$^{-1}$), according to Allan & Castillo (2007).

In Belvedere stream, high nutrient concentrations and electrical conductivity were recorded compared to the other streams. The trophic state index and the Habitat Rapid Assessment Protocol characterized the Belvedere stream as eutrophic and impacted, respectively. Furthermore, evidence of fires was found in the riparian vegetation. These results corroborate those of Souza (2011), who reported, at the same site, a stream that proved to be negatively impacted.

The values of exponent $b$ values for the species studied were within the limits indicated by Vazzoler (1996), ranging from 2.4 to 4.0 for most fish species. According to Verani (1980),

**Figure 3.** Relative Condition Factor ($K_n$) of each species in selected tributaries of Monjolinho River (São Carlos – SP) during the dry season: Espiraiado (Esp1 and Esp2), Canchim (Cch), Belvedere (Bvd), Douradinho (Dr), Ponte de Tábuas (PT1 and PT2) and São Rafael (SR). Different letters represent statistically significant differences between individuals of the same species caught in distinct streams (Kruskal-Wallis test, $p \leq 0.05$, followed by the Dunn multiple comparison test). Same letters correspond to the absence of statistical significance (Kruskal-Wallis, $p > 0.05$). * Statistically different from 1 (Student $t$ test, $p \leq 0.05$) in the stream indicated.

**Figure 4.** Canonical correspondence analysis (CCA) relating the environmental variables, the relative condition factor of the species *Astyanax paranae*, *Phalloceros harpagos* and *Poecilia reticulata* and scores in rapid assessment of habitats of tributaries of Monjolinho river (São Carlos – SP), during dry season. Streams: Espiraiado (Esp1 and Esp2), Canchim (Cch), Belvedere (Bvd), Douradinho (Dr), Ponte de Tábuas (PT1 and PT2) and São Rafael (SR).
variations in this allometric coefficient can be related to environmental conditions and inherent biogenetic features of each species. Thus, the fact that this exponent exceeded 3 indicates that all three species, *Astyanax paranae*, *Phalloceros harpagos* and *Poecilia reticulata* at the study sites, showed a greater weight gain than predicted during growth, featuring positive allometric growth (Wooton, 1991).

In the CCA the relative condition factor (Kn) showed that *Astyanax paranae* was in good condition in the well-oxygenated and less nutrient environments in Espraiado stream, as noted in stretches 1 and 2. However, there were no significant differences in the Kn values between the stretches classified as natural and oligotrophic and those classified as altered and mesotrophic, except for the Ponte de Tábuas stream, stretches 1 and 2, where below average values of Kn were found for this species.

The results found by Lima-Junior (2004) and Orsi (2004) for the species *Astyanax altiparanae* demonstrated a fall in the condition factor at most degraded sites. In contrast, Junior-Martins & Schulz (2001) and Albert et al. (2005) found an increase in Kn for another species of lambari, *Astyanax fasciatus*, in polluted sites. One possible explanation for the higher values of Kn for *Astyanax paranae* found in the subpopulations in Canchim and Douradinho streams, classified as mesotrophic and altered in this study could be that, within certain limits, eutrophication can increase the productivity of an ecosystem (Toledo et al., 1983), in the short term, be beneficial to the species. However, an excessive level of productivity can be harmful because it adversely alters the water quality, causes profound changes in the biogeochemical cycles of aquatic ecosystems and also leads to changes in community structure, destroying the natural balance of the food web (Toledo et al., 1983).

The low Kn values found for the subpopulation in the Ponte de Tábuas stream (stretch 1 and 2) may be related to exposure of *Astyanax paranae* to the high nitrite concentrations recorded when compared to those reported in other streams where this species occurred. According to Baldissertoto (2002), nitrite can be toxic to fish, even at low concentrations, because it combines with the blood’s hemoglobin, hindering the transport of oxygen and resulting in tissue hypoxia (Jensen & Knudsen, 1997). Even at non-lethal levels, it can cause a weakening of the immune system of some species, leading to reduced growth and lower weight gain (Hanson & Grizzle, 1985).

For *Phalloceros harpagos*, the canonical correspondence analysis (CCA) related the species to environments with moderate levels of pollution, which suggests that it is tolerant to environments with moderate disturbance. The relative condition factor did not differ statistically between environments of different degrees of disturbances except for the subpopulation from Douradinho stream. A similar result was obtained by Araújo et al. (2009) for the population of *Phalloceros caudimaculatus* in the Paraíba do Sul River. The low condition factor obtained for the subpopulation of *P. harpagos* in Douradinho stream was possibly a result of competition with *A. paranae*, which occurs in the same stream and in greater numerical density, and the fact that these species have similar trophic niches and a degree of flexibility that allows them to occupy a range of environments, from moderately impacted areas to nearly natural ones (Orsi, 2004). Thus, according to this author, the fish of this genus (*Astyanax* spp.) can use available resources efficiently and can also compete well in moderately disturbed habitats, which can be seen from the higher Kn value of this species in Douradinho stream compared to *Phalloceros harpagos*.

*Poecilia reticulata* was highly correlated with negatively impacted environments, characterized by higher contents of nutrients and low oxygenation of the water. This has already been observed for this species by Lemes & Garutti (2002), Dyer (2003) and Cunico et al. (2006) who reported a high density of this species in impacted streams. According to Oliveira & Bennemann (2005), *Poecilia reticulata* is an exotic species that shows resilience in environments disturbed by human activity, owing to its opportunistic habits and diversified diets. In the present study, the relative condition factor of *P. reticulata* was highest in Belvedere stream, where the most severe conditions of eutrophication were observed, confirming that this species is not affected by poor environmental quality. In general, the species of the order Cyprinodontiformes are more tolerant of environmental degradation and can remain in such sites long after all the other fish disappear (Araújo, 1998; Chapman & Chapman, 1992). According to the authors cited here, the flexibility in the diet and the ability to survive and reproduce in waters with low oxygen facilitate the exploration of the habitat by this fish.

In the streams of the Monjolinho river basin, the varying degrees of environmental quality influenced differently the relative condition factor of the species. *Astyanax paranae* was more sensitive to environments with higher nutrient and oxygen concentrations, while *Phalloceros harpagos* seems to be tolerant, since its condition factor did not differ between environments, with the exception of Douradinho stream, where the Kn value probably reflected the competition for food with *A. paranae*. On the other hand, *P. reticulata* had the highest Kn value in the environment with lowest oxygen and highest nutrient concentrations, suggesting that this species is resistant to disturbed environments. The relative condition factor of fishes, combined with the analysis of environmental conditions, can be a useful tool for studies assessing the environmental quality of streams.

Acknowledgments

We thank CAPES (Coordination for the Improvement of Higher Education Personnel) for the grant to the first author, the technicians, José Valdecir de Lucca e Alcídio Culsó Filho, for their assistance in sampling, and ichthyologists Dr. Alexandre Kannebley de Oliveira and Dr. Evelise Nunes Fragoso de Moura for their contributions.
