PREVENTING TOMORROW’S SUDDEN CARDIAC DEATH IN EPILEPSY TODAY: WHAT SHOULD PHYSICIANS KNOW ABOUT THIS?

Fulvio A. Scorza,1 Diego B. Colugnati,1 Aline P. Pansani,1 Eliza Y.F. Sonoda,1 Ricardo M. Arida,10 Esper A. Cavalheiro1

Approximately 1% of the population has epilepsy, the most common neurological disorder. Moreover, people with epilepsy are more likely to die prematurely than those without epilepsy, and the most common epilepsy-related category of death is sudden unexpected death in epilepsy (SUDEP). Information concerning risk factors for SUDEP is conflicting, but potential risk factors include: age, early onset of epilepsy, duration of epilepsy, uncontrolled seizures, seizure frequency, number of antiepileptic drugs and winter temperatures. Additionally, the cause of SUDEP is still unknown; however, the most commonly suggested mechanisms are cardiac abnormalities during and between seizures. This review discusses the epidemiology, risk factors, etiology, and preventive measures in the management of SUDEP.

KEYWORDS: Epilepsy. Heart. Sudden cardiac death.

EPILEPSY: GENERAL ASPECTS

Epilepsy is the most common serious neurological condition and approximately 50 million people worldwide have it.1 In the US, about 100,000 new cases of epilepsy are diagnosed.2 In the UK, between 1 in 140 and 1 in 200 people (at least 300,000 people) are currently being treated for epilepsy.4 Epidemiological studies suggest that between 70 and 80% of people developing epilepsy will go into remission, while the remaining patients continue to have seizures and are refractory to treatment with the currently available therapies.5,6 The most common risk factors for epilepsy are cerebrovascular disease, brain tumours, alcohol, traumatic head injuries, malformations of cortical development, genetic inheritance, and infections of the central nervous system. In resource-poor countries, endemic infections, such as malaria and neurocysticercosis, seem to be major risk factors.8

Epilepsies are characterized by spontaneous recurrent seizures, caused by focal or generalized paroxysmal changes in neurological functions triggered by abnormal electrical activity in the cortex.9 Because it involves hyperexcitable neurons, a basic assumption links the pathogenesis of epilepsy and the generation of synchronized neuronal activity with an imbalance between inhibitory [g-aminobutyric acid (GABA)-mediated] and excitatory (glutamate-mediated) neurotransmission, in favor of the latter.10 Seizures and epilepsy are usually divided into two groups: partial and generalized. Partial or focal seizures have clinical or EEG evidence of local onset and may spread to other parts of the brain during a seizure, while generalized seizures begin simultaneously in both cerebral hemispheres.8 Temporal lobe epilepsy (TLE) is the most common form of partial epilepsy, probably affecting at least 20% of all patients with epilepsy.11 It is the most common form of drug-refractory epilepsy.12 Atrophy of mesial temporal structures is well-known to be associated with TLE and hippocampal sclerosis,
which is the most frequent histological abnormality in this form of epilepsy.13

SUDDEN UNEXPECTED DEATH IN EPILEPSY

Epilepsy is associated with a two- to three-fold increase in mortality compared to the general population, and sudden unexpected death in epilepsy (SUDEP) is the most important direct epilepsy-related cause of death.8 SUDEP is defined as non-traumatic and non-drowning death in patients with epilepsy that is sudden, unexpected, witnessed or unwitnessed, and with or without evidence of a seizure. Also in SUDEP, post mortem examination does not reveal a toxicological or anatomical cause of death (excluding documented status epilepticus).14 Comparisons of incidence estimates for SUDEP are difficult, since different definitions of SUDEP have been used, not all patients have a postmortem examination, and case ascertainment methods and source populations have varied.15 The incidence of SUDEP has been estimated to be 3.5/1000 person-years in a lamotrigine clinical trial,16 0.5-1.4/1000 person-years in people with treated epilepsy,17 5.9/1000 person-years in outpatients with epilepsy at a tertiary referral center,18 and 0.35/1000 person-years in a population-based study.19 The National General Practice Study of Epilepsy (NGPSE), a community-based study in the United Kingdom, saw the first case of SUDEP after 11,000 person-years of follow-up,20 and the results of the Medical Research Council Antiepileptic Drug Withdrawal Study showed that SUDEP is a rare event among patients with epilepsy in remission.21 Information concerning risk factors for SUDEP is conflicting, but potential risk factors include: early adulthood,16 early onset of epilepsy,22 long duration of epilepsy,23 uncontrolled seizures (mainly in those with TLE),2425 high seizure frequency,2425 certain seizure types,1626 higher numbers of AED222327 and winter temperatures.28 Additionally, potential pathomechanisms for SUDEP are unknown, but it is very probable that cardiac arrhythmias during and between seizures, electrolyte disturbances, arrhythmogenic drugs or transmission of epileptic activity to the heart via the autonomic nervous system potentially play a role.29

CARDIAC ABNORMALITIES AND SUDEP

By definition, the cause of death in SUDEP is currently unknown. A number of postmortem, ictal and interictal cardiac abnormalities do, however, suggest the possibility of seizure-induced cardiogenic SUDEP.2930 Postmortem examinations in people dying of SUDEP have found hearts that are dilated and heavier than expected16293132 and pulmonary edema in approximately 50–86% of cases.16,26,29,32,33 Furthermore, others have described pathological changes in the hearts of those dying with SUDEP, including fibrosis of the walls of small coronary arteries, atrophy of cardiomyocytes, myofibrillar degeneration, edema of the conductive tissue and morphological abnormalities of the cardiac conduction system.2629313435 These abnormalities may be the consequence of repeated hypoxemia and/or may be associated with the increase of catecholamines during an ictal sympathetic storm.293134

Several studies have assessed the frequency and character of ictal cardiac rhythm during seizures,293637 and the most compelling evidence derives from the presence of ictal arrhythmias.30 When ictal cardiorespiratory variables were recorded in people with epilepsy, an increase in heart rate in 91% of 41 seizures and a transient bradycardia in five seizures (four patients) were found.30 Another study evaluated the electrocardiographic (ECG) changes during 51 seizures in 43 patients with refractory epilepsy.39 This showed that 70% of patients had either ECG abnormalities (16%), tachycardias (30%), or both (23%) during the ictal and/or post-ictal period. These changes may all be relevant to the pathophysiology of SUDEP.

Results of interictal cardiac investigations have also been described. In one study, resting ECGs in 75 patients with epilepsy were compared with normal ECGs recorded in age-matched patients without cardiac or neurological disorders; ventricular rate, PR interval, QRS duration, and QT interval (corrected for heart rate) were compared.40 Those with epilepsy had higher heart rates and longer QT durations than the age-matched controls. Heart rate and QT duration were, however, not outside the normal range. Others investigated whether patients with drug refractory epilepsy have cardiovascular abnormalities that might be related to sudden death.41 Twenty-three subjects underwent comprehensive cardiovascular evaluations (ECG, Holter-monitoring, echocardiography, ergometric exercise test and myocardial scintigraphy; if abnormalities were found, coronary angiography was also performed) before and during video-EEG monitoring. ST-segment depression was found in 40%, and this was associated with a higher maximum heart rate during seizures, suggesting that cardiac ischemia may occur in these patients. Although interictal changes in heart rate variability have been described in patients with epilepsy, their contribution to SUDEP remains to be determined.

PREVENTATIVE MEASURES FOR SUDEP BEYOND THERAPIES

Preventative measures other than medical and surgical therapies could be useful in the prevention of SUDEP.
Although the availability of pharmacological treatment of epilepsies has expanded, antiepileptic drugs are still limited in clinical efficacy. Genetic, environmental and social factors, among others, can contribute to the inefficacy of therapeutic outcome in people with epilepsy. Among these factors, nutritional aspects such as omega-3 fatty acid deficiency may play an interesting role. Substantial evidence from epidemiological and case-control studies indicates that omega-3 reduces the risk of cardiovascular mortality, particularly sudden cardiac death. Following this reasoning, as omega-3 fatty acids per se have been shown to reduce cardiac arrhythmias and sudden cardiac deaths, it was hypothesised that omega-3 fatty acid supplementation in patients with refractory seizures may reduce seizures and seizure-associated cardiac arrhythmias, and hence, also SUDEP. Concerning the cardioprotective effects of omega-3, it has long been believed that a daily intake of 3000 to 4000 mg of fish oil supplements or 2 to 3 servings of fatty fish per week are safe and effective in adults in general, including those with neurological diseases. It is very important to emphasise, however, that nutritional therapy, including omega-3 supplementation, is not a substitute for anticonvulsant medications.

Exposure to low temperatures is considered one of the main risk factors for cardiovascular abnormalities and hence, sudden death. There are several findings that may explain the increase in cardiac events in cold temperatures: 1) 53% more cases of acute myocardial infarction are reported during the winter compared with the summer. Most reports, but not all, have demonstrated a significant winter increase in cardiovascular abnormalities and cardiac death, especially in the northern hemisphere where there are extreme winter temperatures. An increase in sudden cardiac death rate has, however, also been reported in the winter in regions where the winters are mild. 2) During the winter, increases in haemoconcentration (erythrocyte count, plasma cholesterol, and plasma fibrinogen levels) have been reported, which could contribute to arterial thrombosis. In this way, rapid coronary deaths could result from rupture of atheromatous plaques during hemodynamic stress related to hypertension and cold-induced coronary spasm. 3) Cold weather can induce a higher systemic vascular resistance with an increase in blood pressure, thus increasing oxygen demand. During a four-year period, the influence of climate on blood pressure in 53 patients with end-stage renal disease treated with haemodialysis was investigated. The authors showed that the mean systolic and diastolic blood pressures were highest during the winter (systolic 153 [SE 3] and diastolic 82 [SE 2] mm Hg) and lowest during the summer (systolic 141 [SE 3] and diastolic 75 [SE 2] mm Hg). 4) The winter temperatures may be associated with flu season, and an increase in upper respiratory tract infections could place stress on the heart. One review noted that the incidence of acute myocardial infarction and atherosclerotic stroke and the incidence of upper respiratory infections (38% of which are due to influenza) both peak in the winter months. It was suggested that, as studies have shown that influenza vaccination is associated with a 50% reduction in incidence of cardiovascular abnormalities and sudden cardiac death, much of this pathology could be prevented by yearly influenza vaccination.

Taking these data into consideration, we believe that cold weather could be considered a new potential risk factor for sudden cardiac death in patients with epilepsy. Moreover, there is an urgent need for several studies (large-scale, prospective, community-based and international) of sudden cardiac death in epilepsy to explore the risk factors and help plan preventative strategies. In the meantime, the use of some medical or non-medical therapies may help to prevent sudden cardiac death in epilepsy. Along those lines, Klone (2004) described some very interesting common-sense and prudent tactics that physicians should consider during the winter time (termed “Merry Christmas Coronary” and “Happy New Year Heart Attack”), especially for patients with established cardiac disease or for those with known risk factors for cardiac disease: 1) instruct patients to avoid delay in seeking medical attention; 2) examine patients if possible, rather than relying upon healthcare providers not familiar with the patients; 3) ensure that coronary care units and emergency departments are adequately staffed; 4) instruct patients to avoid the known triggers for acute myocardial infarction, such as excess physical exertion (especially shovelling show), overeating, lack of sleep, emotional stress, illegal drugs and anger; 5) modify and treat known cardiovascular risk factors; 6) consider aspirin or ß-blockers, or both, if appropriate; 7) instruct patients to avoid exposure to severely cold temperatures; 8) consider flu shots when appropriate.

Others have suggested, since winter mortality in the UK is now not primarily caused by failure to heat homes, the reduction of outdoor cold stress, such as by heating waiting areas for public transport, should be considered. Finally, several suggestions have been made concerning the mechanisms behind SUDEP, most involving speculation about the possible role of autonomic effects such as cardiorespiratory disturbances. It has been believed that cardiovascular diseases are often associated with overactivity of the sympathetic nervous system and that increases in physical activity produce beneficial effects on the cardiovascular system in both normal and diseased individuals via alteration of neural control of the circulation. These effects include reductions in blood...
pressure and sympathetic outflow in humans as well as in animal models of exercise training. Since morbidity and mortality in cardiovascular disease are often associated with elevation of sympathetic nervous system activity, the beneficial effects of physical activity are probably related, in part, to reduction of sympathetic activity. A recent study by our group evaluated the heart rate, in part, to reduction of sympathetic activity. A recent study by our group evaluated the heart rate, in part, to reduction of sympathetic activity. A recent study by our group evaluated the heart rate, in part, to reduction of sympathetic activity.

The results showed differences in the mean heart rate in vivo, but surprisingly, no differences in heart rate could be observed in the isolated ex vivo situation, suggesting a central nervous system modulation of the heart that could explain SUDEP. The results showed differences in the mean heart rate in vivo, but surprisingly, no differences in heart rate could be observed in the isolated ex vivo situation, suggesting a central nervous system modulation of the heart that could explain SUDEP.

Taking these findings together, it is very reasonable to think that regular physical activity is able to attenuate sympathetic nervous system activity, cardiac abnormalities and hence SUDEP. Furthermore, it is clear that premature mortality is increased in patients with epilepsy, particularly in those with more severe seizures, and it is generally acknowledged that the incidence of cardiac abnormalities between seizures is the very probable cause of SUDEP. Since physical activity has been considered to have anticonvulsant effects, it is possible to propose that regular physical activity may attenuate the frequency of seizures and cardiac abnormalities that could culminate in SUDEP.

In conclusion, as reported by others, clarification of risk factors and establishment of the mechanisms of SUDEP are important for establishing preventative measures for SUDEP and for striving for the best control of seizures. However, it is conceivable that encouraging patients with epilepsy worldwide to receive non-pharmacological treatments will lead to substantial public-health benefits.
