ABSTRACT

Clostridium perfringens type A has been incriminated as the etiologic agent in jejunal hemorrhage syndrome (JHS), which is a disease that affects dairy cattle. Although this microorganism is considered an important enteropathogen the pathogenesis of JHS is still not clear, and there have been no reports of its occurrence in Brazil so far. The aim of this study was to describe the occurrence of JHS by infection with a \textit{C. perfringens} type A strain carrying the beta-2 toxin gene in a zebu cow in Brazil, for the first time.

Key words: \textit{Clostridium perfringens}, beta-2 toxin gene, enteropathogen, enteric blood clot.

RESUMO

\textit{Clostridium perfringens} tipo A tem sido considerado agente etiológico da síndrome do jejuno hemorrágico (SJH), que é uma doença que afeta o rebanho de gado. Embora este microrganismo seja considerado um importante enteropatógeno, a patogênese da SJH ainda não foi elucidada, e não havia sido reportada no Brasil até então. O alvo deste estudo foi descrever pela primeira vez a ocorrência da SJH causada por \textit{C. perfringens} tipo A, carreador do gene da toxina beta-2, em um zebuíno no Brasil.

A 33-month-old Gir, from a dairy farm located in Bom Despacho, MG, was treated at the Veterinary Hospital. The cow was in lactation for approximately 120 days, with an average of 55 lb/day. It was being fed with 26 lb/day of a concentrate (16% of protein, corn silage, hay), mineral supplement and \textit{ad libitum} water. The cow presented apathy, a sudden reduction in milk production and dark, sparse and soft stools.

The bovine was subjected to a physical examination, hemogasometry, routine hematology and serum biochemistry. Peritoneal fluid samples were collected to physical and cytological analyses. The animal remained in Veterinary Hospital of Universidade Federal de Minas Gerais (HV-UFMG) for a day, receiving fluidotherapy. With suspicion of bowel obstruction, an exploratory laparotomy was conducted.

Necropsy was performed immediately after death, and intestinal content was collected and sent to the Anaerobics Laboratory- UFMG. The anaerobe bacteriology were performed (SILVA et al., 2013) and characteristic \textit{C. perfringens} colonies were subjected to multiplex (VIEIRA et al., 2008) and netB (necrotic enteritis B-like toxin) PCR (KEYBURN et al., 2008).

Upon physical examination, apathy, bloating, colic, tachypnea (64 breaths min\(^{-1}\)), tachycardia (90 heartbeats min\(^{-1}\)), ruminal atony, and congested ocular and episcleral mucosa vessels were observed. Stools in small quantities with abundant mucus were observed at rectal palpation, they were dark-colored and had a foul odor.
Upon cell blood count, an increase in white blood cells (19,400 cells µL⁻¹) accompanied by an increase in the concentration of metamyelocytes (194 cells µL⁻¹), rods (1,164 cells µL⁻¹), segmented cells (12,416 cells µL⁻¹) and the neutrophil/lymphocyte rate (2.53), featuring a neutrophilic leukocytosis with a left nuclear shift of regenerative-type cells.

Serum biochemistry showed elevated in alanine aminotransferase (ALT-84U L⁻¹) and gamma-glutamyltransferase (GGT-65.9U L⁻¹). The peritoneal fluid was turbid, red and with cytologic predominance of mononuclear and neutrophil cells, which featured an exudate outpouring.

The venous blood gas analysis revealed a high pH (7.5), a base excess of 15mmol L⁻¹, an HCO₃⁻ concentration of 38.1mEq L⁻¹ and a pCO₂ of 79mmHg. This indicated metabolic alkalosis with compensatory respiratory acidosis. Additionally, the potassium and chloride concentrations were low, with values of 3.8 and 87mmol L⁻¹, respectively.

During the exploratory laparotomy, a stretched and diffuse congested small intestine was observed. Death occurred 96 h after onset of the clinical signs. At necropsy, the abomasal mucosa was edematous, hyperemic with multifocal to coalescing linear ulcers (Figure 1A).

The mucosa and serosa of the jejunum were intense and diffusely distended, swollen and had a dark red color (Figure 1B). There was an intraluminal blood clot and in its attached area, the mucosa was liquefied and covered by a dark red liquid. It featured a diffuse, necro-hemorrhagic enteritis associated with the presence of the blood clot (Figure 1C). Six meters after, in the ileum, an intussusception area of 15cm was observed, causing complete bowel obstruction. It was characterized by marked edema and congestion.
Jejunal hemorrhage syndrome in a Zebu cow in Brazil.

The five toxigenic types of \textit{C. perfringens} (A-E) are classified according to the production of four major toxins (alpha, beta, epsilon and iota). Although not crucial to toxynotyping, enterotoxin, netB, and beta-2 toxin are described as additional virulence factors that act synergistically with the major toxins. The involvement of the beta-2 toxin during occurrences of this syndrome is not well defined, but it was suggested that cpb2^+ strains are associated with disease cases, and often culminate in the death of the animals (DENNISON et al., 2002) as we described in the present report. Nevertheless it is necessary more accurate data to associate the gene cpb2^+ and severity of disease.

Presently, there is not enough information to determine the risk factors of the disease. Diets based on a high carbohydrate availability and low fiber content allow the passage of undigested food into the small intestine. This environment promotes bacterial multiplication, which results in the release of large amounts of toxins (FACURY FILHO et al., 2009). Bovine that do not consume by grazing are 100 times more likely to present with JHS than animals with some inclusion level (BERGHAUS et al., 2005). In the USA JHS is less frequent in spring seasons in which there is greater pasture availability (GODDEN et al., 2001).

Other risk factors include: high metabolic stress, high-producing dairy cows, lactation stage, excessively large herds and dominant animals (CECI et al., 2006). Although reports in dairy cattle are more common, it is important to emphasize that it can also occur in confined beef cattle, with no gender predisposition in this case (ABUTARBUSH & RADOSTITS, 2005).

\textit{C. perfringens} rapidly proliferates after the death of the animal and is considered a frequent invader of carcasses. For this reason, diagnoses based on isolations should be carefully analyzed (CECI et al., 2006). In this report, the necropsy and sample collection were performed immediately after the animal’s death. The profuse and almost exclusive growth of the \textit{C. perfringens} colonies after the bacteriological tests indicates that the agent was present in large amounts and that it may be a rust pathogen. The most common clinical signs in JHS cases are poor appetite, dehydration, sudden milk production reduction, depression and melena. In some cases, hypothermia, mucous hypochromic, ruminal hypomotility, tachycardia, tachypnea, abdominal distension and pain can be observed in the affected cattle. Upon rectal palpations, distended bowels (jejunum, cecum and colon), a reduction in the amount or absence of feces and the presence of blood clots in the stool are usually observed. (DENNISSON et al., 2002). The clinical findings described in the present report are consistent with those previously reported in the literature, but unfortunately, there are no pathognomonic clinical signs and they often overlap those of other diseases.

The ileal intussusception reported is a very important confounder. The lack of necrosis of the intestinal loop involved in intussusception nor fibrin deposition demonstrate that was an acute process. Probably, the intussusception occurred after occurrence JHS, due to decreased or absent peristalsim of the injured area. This assumption is suported by PEARSON (1971), who reports that distention of intestinal segments, enteritis, alterations in intestinal motility, hypomotility or hypermotility, are considered predisposing factors for the development of intussusception in cattle.

Among the hematological findings, leukocytosis may be explained by the rapid release...
of neutrophils from hematopoietic organs to the site of infection. The increase in liver enzymes (ALT and GGT) can be attributed to the liver damage caused by the circulating toxins that invaded through the intestinal mucosa. Metabolic alkalosis associated with compensatory respiratory acidosis, hypokalemia and hypochloremia are expected due to the extent of bowel obstruction. The functional or mechanical obstruction of the small intestine may have contributed to the the installation of a hypokalemic alkalosis and hypochloremia. Hypokalemia may also have been caused by lack of appetite. The clinical signs reflect the acute nature of JHS and the secondary intestinal stasis (CECI et al., 2006).

In general, animals that develop JHS die within 24 to 36h after the onset of clinical signs, and no effective treatments have been described. There is no scientific evidence of the efficacy of vaccination in preventing this syndrome (LEJEUNE, 2004). Prevention is therefore based on providing quality food and an adequate ratio of concentrate and roughage.

Although JHS had not yet been described in Brazil, the association between epidemiological, clinical, gross and bacteriological findings allow for the first firm diagnosis of this syndrome due to C. perfringens type A cph+ in zebu in the country.
