Abstract

Cleidocranial dysplasia (CCD) is an autosomal dominant human skeletal disorder comprising hypoplastic clavicles, wide cranial sutures, supernumerary teeth, short stature, and other skeletal abnormalities. It is known that mutations in the human RUNX2 gene mapped at 6p21 are responsible for CCD. We analyzed the mutation patterns of the RUNX2 gene by direct sequencing in six Taiwanese index cases with typical CCD. One of the patients was a familial case and the others were sporadic cases. Sequencing identified four mutations. Three were caused by single nucleotide substitutions, which created a nonsense (p.R391X), two were missense mutations (p.R190W, p.R225Q), and the forth was a novel mutation (c.1119delC), a one-base deletion. Real time quantitative PCR adapted to determine copy numbers of the promoter, all exons and the 3'UTR region of the RUNX2 gene detected the deletion of a single allele in a sporadic case. The results extend the spectrum of RUNX2 mutations in CCD patients and indicate that complete deletions of the RUNX2 gene should be considered in those CCD patients lacking a point mutation detected by direct sequencing.

Key words: cleidocranial dysplasia, CCD, RUNX2, RUNX2 deletion mutation.

Received: June 23, 2010; Accepted: December 12, 2010.

Cleidocranial dysplasia (CCD, MIM#119600), is an autosomal dominant skeletal dysplasia comprising defective skull ossification with frontal bossing, open fontanels, clavicular hypoplasia, delayed ossification of the pelvis, late eruption of permanent teeth, malformed dental roots, supernumerary teeth, and normal intelligence (Mundlos, 1999).

Mutations in the core-binding factor A1 gene (CBFA1) located on chromosome 6p21 were identified as the cause of CCD (Gelb et al., 1995; Mundlos et al., 1997). This gene is composed of eight exons and spans a region of more than 220 kb in 6p21. The CBFA1 protein contains a highly conserved runt domain and therefore, the gene is also referred to as RUNX2 (GenBank accession number AF001450) (Yoshida et al., 2002). The runt domain interacts with the core binding factor consensus sequence TG^3/C/GGT located in the promoter region of target genes. RUNX2 regulates the expression of multiple genes expressed in osteoblasts and it is a cis-acting element in the osteocalcin promoter (Ducy et al., 1997). RUNX2 knockout mice show a complete lack of bone formation, whereas heterozygous RUNX2 mutated mice display some of the hallmarks of human CCD, including open fontanelles and hypoplastic clavicles, but not the dental anomalies (Otto et al., 1997).

The RUNX2 protein contains two regions divided by the runt domain. On the N-terminal side of the runt domain are glutamine-alanine repeats (Q/A domain) and on the C-terminal side is a region rich in proline-serine-threonine (PST domain). The PST domain is thought to be the transactivation domain. The last five amino acids of RUNX2 (VWRPY) compose a conserved motif in all runt proteins (Quack et al., 1999; Zhang et al., 2000; Otto et al., 2002).

Several mutations of RUNX2 were identified in patients with CCD (Otto et al., 2002). In this study, we screened six patients with typical CCD for mutations in the RUNX2 gene. Mutations were detected in five cases, these including an entire deletion of the RUNX2 coding region.

The six unrelated patients included in this study were first evaluated because of short stature. They received the clinical diagnosis of CCD (for review of diagnostic criteria, see Mundlos, 1999). Patient 4 was a familial case, whereas
the others were sporadic. Except for Patients 5 and 6, their height was below the 5th centile for the Taiwanese population. All patients showed brachycephaly, mild frontal bossing, late tooth eruption with multiple crowded and supernumerary teeth, as well as clavicular hypoplasia. The upper part of the thorax was small and a funnel chest was noted. Scoliosis of the thoracic spine with convexity to the right and mild lordosis were also found. Chest radiographs showed hypoplasia of the clavicles with absence of the outer half. Three-dimensional head CT revealed enlarged anterior fontanelles beyond two years of age. Physical data for the six patients are summarized in Table 1.

Informed consent was obtained from the patients or the guardians of these patients. Genomic DNA was extracted from peripheral blood leukocytes using a MagNA Pure LC DNA Isolation Kit (Roche, Mannheim, Germany). The complete RUNX2 coding region, including intron/exon boundaries, promoter region and 3’UTR were amplified according to Quack et al. (1999) and Napierala et al. (2005). PCR products were purified from the agarose gel using a QIAEX II kit (Qiagen, Hilden, Germany) and subjected to direct sequencing using a BigDye 3.1 Terminator cycle sequencing kit (Applied Biosystems, Forst City, CA, U.S.A.) with ABI Prism 377 DNA Sequencer or ABI 3100 Genetic Analyzer (Applied Biosystems, Forst City, CA, U.S.A.). To determine carrier rates for the novel mutations in the Taiwanese population, the RUNX2 gene profile of 100 healthy individuals was analyzed using the same procedures. Reference sequence and base-pair numbers refer to GenBank accession numbers AF001443-AF001450 and NM_001024630.

RUNX2 mutations were detected in four patients. Patient 1 was heterozygous for a C-to-T transition at cDNA nucleotide position 1171 in exon 7 of RUNX2, this creating a stop codon at amino acid position 391 (p.R391X). The nonsense mutation, which caused early termination and produced a truncated protein lacking the PST-domain and the VWRPY motif (Thirunavukkarasu et al., 1998), has been previously reported (Tsai et al., 2000; Zhang et al., 2000). The mutation seen in Patient 4 was in heterozygosis and represented a C-to-T transition at nucleotide 568 in exon 1 of RUNX2, this causing the substitution of arginine by tryptophan at amino acid position 190 (p.R190W) in the runt domain (Otto et al., 2002). An arginine stretch located in the runt domain plays an important role in DNA binding. Therefore, disruption of this region may lead to the loss of DNA binding ability (Yoshida et al., 2002). As the side chain of arginine is the major part that interacts with DNA, replacing it by another amino acids of different hydrophobicity and charge, such as tryptophan, disrupts the structure of the runt domain and decreases DNA binding affinity.

Patient 6 was heterozygous for a G-to-A transition at cDNA nucleotide position 674 in exon 3 of RUNX2, this causing arginine to be substituted by glutamine at amino acid position 225 (p.R225Q) at the C-terminal end of the runt domain (Otto et al., 2002). This amino acid substitution abolishes the positive charge of the residue at this position and might affect the structure stability and interaction with other proteins.

In Patient 2, the cytosine at cDNA nucleotide position 1119 was deleted (c.1119delC), which led to a frameshift at amino acid 373, creating a stop codon at position 483 (Figure 1). This deletion has not been reported previously and was not present in the patient’s parents. It disrupts both the repression subdomain and the VWRPY motif and is predicted to abolish RUNX2 function. The C-terminal region of the PST-domain, which contains a region that interacts with Smad proteins, is considered necessary for RUNX2-mediated transcriptional regulation (Zhang et al., 2000). The VWRPY motif is an interaction partner for the binding of transcriptional corepressors of the TLE/Grg family (Aronson et al., 1997; Levanon et al., 1998). Thus, even in cases where the runt domain is complete, the mutated RUNX2 protein may fail to interact with other transcription factors (Thirunavukkarasu et al., 1998; Zhang et al., 2000).

In Patient 2, we furthermore found a single nucleotide polymorphism at cDNA nucleotide 240 (p.A80A), a substitution of G for A. This polymorphism site was described previously in another population (Machuca-Tzili et al., 2002).

Patients 3 and 5 did not show any mutation in the promoter and the coding regions of RUNX2, similar to previous results showing that only 33–50% of patients with an unambiguous clinical and radiographic diagnosis of CCD carry mutations in the RUNX2 gene (Quack et al., 1999). Large deletions or duplication of the RUNX2 gene are rarely seen in CCD patients (Lee et al., 2008). Thus, to investigate the possibility of a gross RUNX2 deletion, the genomic DNA of Patients 3 and 5 were subjected to real time quantitative PCR (RT-qPCR), following the analytical conditions described by Lee et al. (2008). Briefly, three independent experiments were performed to determine copy number variation in CCD patients and normal individuals. The RT-qPCR primers were designed to detect the promoter, exons, and 3'UTR regions of RUNX2. The glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene was used as control. The formula for calculating copy number was: copy number = \(2 \times 2^{(-\Delta C_{\text{tp}} - \Delta C_{\text{tn}})}\) where Ct is the threshold cycle defined as the mean cycle at which the fluorescence curve reached an arbitrary threshold; \(\Delta C_{\text{t}}\) is calculated as Ct of RUNX2 - Ct of GAPDH, \(\Delta C_{\text{tp}}\) is the \(\Delta C_{\text{t}}\) for patients, and \(\Delta C_{\text{tn}}\) that for normal individuals. While two copies of the tested RUNX2 regions were present in Patient 5, Patient 3 had only one copy of these regions (Figure 2). Thus, we concluded that Patient 3 carried a deletion of one of the RUNX2 alleles.

Although no mutation was found in Patient 5, following sequencing and RT-qPCR analysis, these result do not exclude other mutation types in the RUNX2 gene, such as inversions, translocations, mutations within introns, etc. On the other hand, a report showed that cytogenetic anomalies at chromosomal band 8q22 have been associated with a CCD-like phenotype case (Bruton et al., 1992). Thus, more detailed analyses are required to identify the genetic abnormality seen in Patient 5.

The patients with any of the four point mutations in the RUNX2 gene were similar in their clinical symptoms, independent of whether their RUNX2 protein retained the normal runt domain or not. The patients presented here lacking the PST domain and VWRPY motif exhibited typical CCD. This suggests that the C-terminal region plays an important role in RUNX2 function, with different genotypes seemingly generating a similar CCD phenotype. From the findings of Patient 3, who carried the deletion of one allele, we conclude that a one-allele deletion affects the gene expression level and produces clinical symptoms similar to those of point mutations. We furthermore inferred that CCD patients not showing a RUNX2 mutation in directed sequence data should be screened for a gene deletion or duplication, and RT-qPCR appears as a sensitive approach to this end.
