Case Report

Kikuchi-Fujimoto disease*

Doença de Kikuchi-Fujimoto

Rogério Gastal Xavier¹, Denise Rossato Silva², Mauro Waldemar Keiserman³, Maria Francisca Torres Lopes⁴

Abstract

Kikuchi-Fujimoto disease is characterized by fever and lymphadenopathy, usually localized in the cervical region. This disease principally affects young females. It can be confused with lymphoma, adenocarcinoma metastasis and tuberculosis. We report two cases of Kikuchi-Fujimoto disease. In the first case, a 28-year-old female had been treated for tuberculosis one year prior and presented with a clinical and histological profile consistent with Kikuchi-Fujimoto disease. The second patient, a 58-year-old female, initially received treatment for Wegener’s granulomatosis and, subsequently, for tuberculosis. Histopathological examination followed by immunohistochemical analysis confirmed the diagnosis of Kikuchi-Fujimoto disease in both cases. After the definitive diagnosis had been made, both patients were treated symptomatically, and both presented clinical improvement within one month. Subsequently, the latter patient developed systemic lupus erythematosus.

Keywords: Fever; Lymph nodes; Rare diseases; Tuberculosis, lymph node; Histiocytic necrotizing lymphadenitis; Lupus erythematosus, systemic.

Introduction

Kikuchi-Fujimoto disease (KFD), also known as Kikuchi’s disease or necrotizing granulomatous lymphadenitis, is rare, has a benign course and is of unknown cause. The disease was initially described in 1972, in Japan, in young females affected by fever and cervical lymphadenopathy.(2) Although its pathogenesis remains little understood, it is thought to be a hyperimmune reaction induced by different antigenic stimuli or an autoimmune process in which apoptosis play an important role.(3) Most patients are under 40 years of age and were previously healthy. The male/female ratio is as high as 1:4 in some studies,(1) although other studies have shown little gender bias.(4)

The onset of the disease is acute or subacute, progressing over the course of two to three weeks.(5) The most common form of presentation is lymphadenopathy, usually localized in the cervical region. This disease principally affects young females. It can be confused with lymphoma, adenocarcinoma metastasis and tuberculosis. We report two cases of Kikuchi-Fujimoto disease. In the first case, a 28-year-old female had been treated for tuberculosis one year prior and presented with a clinical and histological profile consistent with Kikuchi-Fujimoto disease. The second patient, a 58-year-old female, initially received treatment for Wegener’s granulomatosis and, subsequently, for tuberculosis. Histopathological examination followed by immunohistochemical analysis confirmed the diagnosis of Kikuchi-Fujimoto disease in both cases. After the definitive diagnosis had been made, both patients were treated symptomatically, and both presented clinical improvement within one month. Subsequently, the latter patient developed systemic lupus erythematosus.

tuberculosis, treatment with the RHZ regimen was resumed, and, after the onset of skin rash, pyrazinamide was replaced with ethambutol. The treatment was discontinued 30 days later due to the lymph node biopsy results: there was a xanthogranulomatous and necrotizing inflammatory process, without granuloma formation and with an extensive population of (CD68+) xanthomatous histiocytes; as well as negativity for AFB and fungi. The findings were not suggestive of tuberculosis, and, therefore, the possibility of KFD was considered. The patient was treated symptomatically, and there was improvement of arthralgia, together with resolution of the fever, within 30 days. After 18 months, the patient no longer presented clinical alterations or ANF.

Case 2

A 58-year-old female nonsmoker reported cough, moderate weight loss, fatigue and joint pain. The patient had a history of childhood asthma. After age 40, she experienced recurrence of the asthma—a fact that she attributed to contact with paints and solvents in the workplace. The patient used inhaled...
formoterol and budesonide (12/400 µg) daily, achieving satisfactory symptom control. A chest X-ray and a tomography scan of the chest showed bilateral consolidations and bronchiectasis in the lower lobes (Figure 1). Laboratory tests revealed the following: hematocrit, 41.1%; hemoglobin, 13.7 g/dL; leukocytes, 8,970, with lymphopenia (1,076 lymphocytes); ANF, present (1:160), with a dotted nuclear pattern; ESR, 56 mm/h; and C-reactive protein, 27.60 mg/L. At the time, Wegener’s granulomatosis was suspected due to antineutrophil cytoplasmic antibody (ANCA) serum positivity. There was no upper airway involvement. Cyclophosphamide treatment was started. In the first month, there was an increase in the left anterior cervical ganglion. The lymph node biopsy identified chronic granulomatous lymphadenitis with extensive noncaseating necrosis (Figure 2). Testing for AFB was negative. Since tuberculosis was suspected, the patient received the RHZ regimen for 6 months, presenting clinical involvement. However, in the following two years, the patient continued to experience fatigue, joint pain and well-defined episodes of pneumonia, as well as, during the final 6 months, oral lesion at the base of the tongue. She used systemic corticosteroids and antibiotics temporarily (5 to 6 times, for 10 to 14 days). With the worsening of the symptoms, the patient again sought treatment. Laboratory tests showed the following: ANF, 1:80 (homogeneous nuclear pattern); anti-DNA, nonreactive; lymphopenia; and ESR, 65 mm/h. A review of the anatomopathological diagnosis confirmed chronic granulomatous lymphadenitis with necrosis, numerous vacuolated histiocytes and giant Langerhans-type cells, as well as negativity for AFB and fungi. In addition, an immunohistochemical panel was performed, revealing CD68 (KP-1) positivity (xanthomatous histiocytes) and myeloperoxidase negativity, which is suggestive of KFD. The patient was then diagnosed as presenting a combination of KFD (which had gone undiagnosed for two years) and systemic lupus erythematosus (SLE). Her condition was controlled by the addition of oral azathioprine (100 mg/day) and prednisone (40 mg/day), the latter being tapered to discontinuation. Within 30 days, the patient presented clinical improvement, as well as improved laboratory test and tomography results.

Discussion

Here, we have described two cases of KFD. The actual incidence of this disease is estimated to range from 0.5% to 5% of all cases of adenopathy analyzed histologically. In a retrospective
study of 1,724 lymph node biopsy samples, KFD was found in 36 cases.[6] Various infectious agents, such as Epstein-Barr virus, herpes virus 6, herpes virus 8, parvovirus B19, parainfluenza virus, Yersinia spp. and toxoplasma, have been proposed as antigenic stimuli.[1] In our report, both patients presented bilateral consolidations, consistent with an infectious or inflammatory process. Although no infectious germs were identified, it is possible that this was the antigenic stimulus for the development of KFD.

Typical cases usually occur in young females, as was the case of the first patient (28 years old). However, patient ages range from 6 to 80 years.[1] Fever is the initial symptom in 30% to 50% of patients. Symptoms such as fatigue, joint pain, skin rash, arthritis and hepatosplenomegaly are also found. Leukopenia, increased ESR and anemia are some of the laboratory findings reported. Systemic symptoms are more prominent in cases of extranodal involvement.[1] The first patient developed skin rash, which was initially attributed to an adverse effect of the antituberculous drugs, although one cannot rule out the possibility that it was secondary to KFD.

There are some characteristics, such as gender and age, as well as histological alterations, that KFD and SLE have in common, some authors considering the former to be a lupus-like syndrome.[1] It has been proposed that KFD is a manifestation of, or evolves to, SLE,[4] justifying the surveillance of KFD patients using immunological studies such as ANF testing. Patients can present positivity for ANF, anti-ribonucleoprotein, anti-DNA and lupus anticoagulant.[17] Our two patients presented ANF. The second patient presented ANCA positivity at the onset of the condition. We found no descriptions of cases of KFD with ANCA positivity. However, it is known that these antibodies can be present in various autoimmune diseases, such as SLE, and the second patient described here subsequently developed SLE. Other autoimmune conditions, such as antiphospholipid antibody syndrome, polymyositis, Still’s disease, uveitis, scleroderma, thyroiditis, pulmonary hemorrhage and interstitial lung disease, can be associated with KFD.[5,17]

There can be diagnostic confusion with lymphoma and adenocarcinoma metastasis.[10] The differential diagnosis of KFD should include SLE, lymphoma, adenocarcinoma, infection with Yersinia spp., toxoplasmosis, mononucleosis, AIDS, vasculitis and Kawasaki disease.[19] Due to multisystemic involvement and spontaneous resolution of lymphadenopathy, sarcoidosis can also be included in the differential diagnosis.[19]

One group of authors described the case of a patient with KFD and concomitant pulmonary tuberculosis.[20] Cases have also been reported in India. However, in countries with a high prevalence of tuberculosis, the concomitant diagnosis of tuberculosis should be well investigated.[1,14]

Histologically, KFD is characterized by ganglia with foci of paracortical necrosis surrounded by aggregates of histiocytes.[6] Three histological profiles, which might correspond to evolutional or sequential phases, to different etiologic agents or even to differences in the inflammatory responses of patients, have been described: proliferative, necrotizing and xanthomatous.[18]

One group of authors described 25 cases of KFD. In that study, two patients had undergone chemotherapy for the treatment of lymphoma, and two patients were treated with antituberculous drugs prior to the receipt of the biopsy results.[3] In the first case reported here, the patient received treatment for Wegener’s granulomatosis and for tuberculosis before the final diagnosis was made. Since empirical treatment is potentially toxic, it is important to consider KFD in the differential diagnosis of cervical lymphadenopathy in young females.

There is no effective treatment. The signs and symptoms usually resolve within 4 months.[5] Patients with more severe or persistent symptoms have been treated with corticosteroids. Long-term follow-up evaluation should be performed due to disease recurrence (in up to 3% of the cases) and to the possibility of SLE development.[1,18] Our second patient developed SLE during a two-year follow-up period.

The presence of fever and cervical lymphadenopathy, especially in young females, should raise the suspicion of KFD.
