Three different Ti-based alloys with bcc structure and Laves phase were studied. The TiCr$_{1.1}$V$_{0.9}$, TiCr$_{1.1}$V$_{0.45}$Nb$_{0.45}$ and TiCr$_{1.1}$V$_{0.9}$ + 4%Zr,Ni$_{10}$ alloys were melted in arc furnace under argon atmosphere. The hydrogen absorption capacity was measured by using apparatus type Sievert’s. Crystal structures, and the lattice parameters were determined by using X-ray diffraction, XRD. Microstructural analysis was performed by scanning electron microscope, SEM and electron dispersive X-ray, EDS. The hydrogen storage capacity attained a value of 3.6 wt. (%) for TiCr$_{1.1}$V$_{0.9}$ alloy in a time of 9 minutes, 3.3 wt. (%) for TiCr$_{1.1}$V$_{0.45}$Nb$_{0.45}$ alloy in a time of 7 minutes and 3.6 wt. (%) TiCr$_{1.1}$V$_{0.9}$ + 4%Zr,Ni$_{10}$ with an increase of the hydrogen absorption kinetics attained in 2 minutes. This indicates that the addition of Nb and 4%Zr,Ni$_{10}$ to the TiCrV alloy acts as catalysts to accelerate the hydrogen absorption kinetics.

Keywords: transition metal compound, hydrogen absorbing materials, crystal structure

1. Introduction

The hydrogen economy has three important aspects to their success: production, transport and storage. Metal hydrides are a safe and economical way to store hydrogen compared to pressurized tanks and cryogenic storages. Cho et al.\(^2\), showed that alloys with bcc structure, particularly TiVCr system have the advantage of absorbing large amounts of hydrogen at room temperature. Dos Santos et al.\(^3\), studying the TiVCr system, observed that TiCr$_{1.1}$V$_{0.9}$ alloy attains a weight percentage of 3.55 wt. (%) at 298 K being considered a possible candidate for use in a practical way. However, there are several problems to be solved in order to make these alloys useful for hydrogen storage such as the slow kinetics of absorption/desorption and the high temperature of desorption. Ball milling techniques and different catalysts have been used to improve the hydrogen absorption/desorption, such as LaNi$_{5}$ and FeV, but the capacity decreases by contamination and diminution of lattice parameter\(^4\). Chen et al.\(^5\) demonstrated that the Laves phase acted as a catalyst to accelerate the kinetics of hydrogen absorption/desorption of the bcc solid solution phase.

In the present work the effects of the addition of Zr,Ni$_{10}$ and Nb into the TiCr$_{1.1}$V$_{0.9}$ alloy were analyzed by their hydrogen absorption/desorption properties.

2. Experimental Procedure

The alloys with the following compositions TiCr$_{1.1}$V$_{0.9}$, TiCr$_{1.1}$V$_{0.45}$Nb$_{0.45}$, Zr$_{10}$Ni$_{10}$ were melted separately. The TiCr$_{1.1}$V$_{0.9}$ alloy was co-melted with 4% of Zr,Ni$_{10}$. All samples were synthesized by arc melting under argon atmosphere using high purity elements (>99.95%). The samples were remelted at least three times to ensure a good homogeneity. The alloys ingot were mechanically pulverized in air to a diameter size that was less than 30 µm. Crystal structure and lattice parameters were analyzed by XRD using a Shimadzu 5000 with Cu-Kα radiation. The microstructure was studied by SEM, coupled to an electron dispersive X-ray, EDS, JEOL JSM 6460 LV. The hydrogen absorption/desorption properties of the as-cast sample were measured in a Sievert’s type apparatus (PCT pro 2000). The activation of the samples was carried out in an autoclave where vacuum was maintained for 2 hours at 573 K, the main objective is to remove any oxide layer and surface water ensuring the initial activation of the sample.

3. Analysis and Results

X-ray patterns indicates that TiCr$_{1.1}$V$_{0.9}$ alloy presents a single phase bcc structure with lattice parameters of 3.060 Å (Figure 1a). When Nb is added to the TiCr$_{1.1}$V$_{0.9}$ alloy higher intensity peaks characteristics of the bcc structure and a minor peak corresponding to a second phase identified as Laves phase C14 (Figure 1b). The lattice parameter for the bcc phase is 3.099 Å. This increase, compared with TiCr$_{1.1}$V$_{0.9}$ alloy, is due to the fact that both the atomic radius Ti (132 pm) as the Nb (134.2 pm) are greater than the atomic radius of Cr (117.2 pm) and V (122.4 pm). This leads to increase lattice parameter of the TiCr$_{1.1}$V$_{0.45}$Nb$_{0.45}$ alloy. Moreover when 4% of the intermetallic Zr,Ni$_{10}$ is added as co-melt to the TiCr$_{1.1}$V$_{0.9}$ alloy two coexisting phase are observed (Figure 1c). A greater intensity corresponding to the bcc structure and the second phase with Laves phase...

C14 structure as the same is observed. The lattice parameter for the bcc structure is 3.041 Å. This decrease of the lattice parameter compared with the lattice parameter of the TiCr\textsubscript{1.1}V\textsubscript{0.9} alloy is mainly due to the diffusion of Ti atoms of the main bcc phase for the secondary phase. This is verified by EDS semiquantitative analysis whose values are shown in Table 1. Therefore less Ti atoms are in bcc phase, this is in accordance with Vegard law which describes the increase or decrease of the crystal lattice parameter as a function of the concentrations of the constituent elements\textsuperscript{7}.

The samples as melted were analysed by SEM and semiquantitative EDS. Figure 2 shows the microstructure of the TiCr\textsubscript{1.1}V\textsubscript{0.9}, TiCr\textsubscript{1.1}V\textsubscript{0.45}Nb\textsubscript{0.45}, and TiCr\textsubscript{1.1}V\textsubscript{0.9}+4%ZrNi\textsubscript{10} alloys. The corresponding micrograph of the TiCr\textsubscript{1.1}V\textsubscript{0.9} alloy (Figure 2a) shows an homogeneously distributed phase. This phase is rich in Ti and Cr according to analysis performed by EDS. The micrograph shown in Figure 2b, corresponds to TiCr\textsubscript{1.1}V\textsubscript{0.45}Nb\textsubscript{0.45} alloy which presents a dendritic microstructure that consists of two phases a light gray and the other a medium gray at the grain boundary. Analysis done by EDS shows a Ti-Cr rich-phase and the other Nb-V rich-phase.

Figure 2c show the microstructure for corresponding TiCr\textsubscript{1.1}V\textsubscript{0.9}+4%ZrNi\textsubscript{10} alloy where it can be seen the presence of two phases being one Ti-rich phase and the second rich in Zirconium and Nickel as analyzed by EDS. The analysis performed by SEM show consistency with the analyses done by XRD which mainly shows the presence of bcc phase and other presented two structures coexisting bcc phase and the Laves phase C14.

Figure 3 shows the hydrogen absorption capacity and the time to reach the maximum hydrogen for different samples. An important parameter in this type of alloy is the incubation time which is the time needed so that the hydrogen breaks the oxide layer and therefore the permeate

Figure 2. SEM image of the a) TiCr\textsubscript{1.1}V\textsubscript{0.9}, b) TiCr\textsubscript{1.1}V\textsubscript{0.45}Nb\textsubscript{0.45}, c) TiCr\textsubscript{1.1}V\textsubscript{0.9}+4%ZrNi\textsubscript{10}.
through the bulk. It is important to note that all samples were previously subjected to the activation process to remove and oxide layer. For the TiCr\textsubscript{1.1} V\textsubscript{0.9} incubation time is 32 minutes and the time needed to reach the maximum capacity is 9 minutes, this is because a layer of oxide on the surface still remains. When Nb is added to the TiCr\textsubscript{1.1} V\textsubscript{0.45} alloy, the incubation time decreases to 10 minutes reaching a maximum hydrogen capacity absorption in 7 minutes. This suggests that the dendritic intergranular phase precipitated acts as preferred site for the diffusion of hydrogen caused either by short-circuit of diffusion which benefits the rapid formation of hydrogen. This short-circuit mechanism were described by J. Philibert\textsuperscript{8}. For the TiCr\textsubscript{1.1} V\textsubscript{0.9} + 4\%Zr\textsubscript{7}Ni\textsubscript{10} the incubation time decrease to 30 seconds reaching a maximum hydrogen capacity absorption in a time of 2 minutes. This phenomenon is due to the hydrogen permeates through the first oxide layer of the Laves phase C14 having a thickness less than the bcc phase, this behavior was also described by Zhouming et al.\textsuperscript{9}. This leads cracking along the grain boundaries resulting in exposure of new surfaces; therefore, more hydrogen can penetrate into the alloy bulk, as was observed by Pei et al.\textsuperscript{10}. So this indicates that the additives Nb an 4\%Zr\textsubscript{7}Ni\textsubscript{10} act as catalysts mainly due to the formation of Laves phase that induces a rapid reaction with hydrogen, allowing easy pulverization compared with alloys of bcc structure which exhibit high hardnes.

The hydrogen absorption capacity for the TiCr\textsubscript{1.1} V\textsubscript{0.9} alloy reach a maximum of 3.6 wt. (%) for the TiCr\textsubscript{1.1} V\textsubscript{0.45}Nb\textsubscript{0.45} alloy the hydrogen absorption capacity was 3.3%, although the lattice parameter of 3.09 Å is a larger than the TiCr\textsubscript{1.1} V\textsubscript{0.9}, 3.06 Å. Therefore, the decrease of the capacity is due to the formation of the Laves phase C14 that competes with the bcc structure phase. When adding 4\% Zr\textsubscript{10}Ni\textsubscript{10} the hydrogen capacity absorption remains constant with a value of 3.6 wt. (%). In this case, the small amount of the intermetallic does not affect the total capacity, also that the addition of Zr has a high affinity with hydrogen.

at temperatures higher than 670 K and 360 K, respectively, due to the stronger bond Ti-H that has a bond dissociation enthalpy of 782 kJ.mol\textsuperscript{-1}\textsuperscript{12} compared to Cr-H value that is of 752 kJ.mol\textsuperscript{-1}\textsuperscript{12}. However, in Figure 4, the performance increases at 375 K where better results were obtained for TiCr\textsubscript{1.1} V\textsubscript{0.9} and TiCr\textsubscript{1.1} V\textsubscript{0.45}Nb\textsubscript{0.45} whose value is 1.5 and 1.4 wt. (%) respectively.

4. Conclusions

The addition of Nb and Zr\textsubscript{7}Ni\textsubscript{10} acts as a good catalyst and improves significantly the hydrogen absorption kinetics due to the formation of Laves phase. From the practical point of view these catalysts decrease the incubation time allowing that the different alloys do not have to use several hydrogenation processes at high temperatures and this is reflected in an energy saving. The capacity of absorption is approximately 3.6 wt. (%) at room temperature and the performance of desorption of hydrogen increases with temperatures above 375 K.
