The composite Ag₃PO₄/CeO₂ photocatalyst, a novel p-n type heterojunction, has been successfully fabricated through a facile hydrothermal process combined with a successive in situ precipitation technique. The X-ray diffraction (XRD), scanning electron microscopy (SEM), high-resolution transmission electron microscopy (HRTEM), and UV-visible diffuse reflectance spectra (DRS) were used to characterize the as-obtained products. The SEM and TEM image show that CeO₂ particles have been successfully loaded and well distributed in the surface of Ag₃PO₄. The photocatalytic activities of the p-Ag₃PO₄/n-CeO₂ heterojunctions were investigated for their efficiency on the degradation of Rhodamine B (RhB) under ultra-violet light and visible light irradiation, and the results showed that the p-Ag₃PO₄/n-CeO₂ heterojunctions possessed remarkable photocatalytic activities. The enhanced photocatalytic activity can be attributed to the extended absorption in the visible light region resulting from the Ag₃PO₄ and the effective separation of photogenerated carriers driven by the internal electrostatic field in the junction region.

Keywords: P-n junction, Semiconductors, Photocatalytic activity

1. Introduction

As a result of an imminent energy crisis and growing pollution issues, many researchers are aiming at the utilization of renewable energy sources such as wind or solar light¹. Among all the approaches for renewable energy utilization, one of the most remarkable one is the use of solar energy for photocatalytic degradation of organic pollutants and for hydrogen generation via water splitting². However, some traditional photocatalysts such as TiO₂, ZnO, NiO can absorb only ultraviolet light due to their wide band gaps. Thus, the development of visible-light-driven (VLD) photocatalysts has attracted increasing attention in order to efficiently utilize solar light in the visible region (700 nm > λ > 400 nm). Recently, Ye and co-workers reported that Ag₃PO₄ semiconductor exhibited a high-efficient usage of visible light (up to 90%) for O₂ evolution from water as well as effective photodecomposition of organic compounds³⁴. Unfortunately, one major limitation of this novel photocatalyst is unstable upon photo-illumination, and it is easily corroded by the photogenerated electrons (4Ag₃PO₄ + 6H₂O + 12h⁺ + 12e⁻ → 12Ag + 4H₃PO₄ + 3O₂)³. Therefore, a key issue is how to enhance the stability of Ag₃PO₄ photocatalyst by improving the separation efficiency of the photogenerated electrons and holes.

It has been reported that coupling two or more semiconductors with appropriate band positions is an efficient strategy to effectively enhance the photocatalytic activities of the semiconductor photocatalysts, because it can improve the separation efficiency of photogenerated electron-hole pairs and solar light absorption ability⁶.⁷. In particular, the fabrication of a p-n junction photocatalyst is believed to be very effective strategy to significantly enhance the photocatalytic activity of photocatalysts because of the existence of an internal electric field⁸. For instance, it has been reported that BiOI/SnS₂ heterojunction flowerlike structure demonstrate an enhanced visible-light photocatalytic activity due to the formation of the p-n junction between p-type BiOI and n-type SnS₂⁹. Cerium dioxide (CeO₂) is an n-type semiconductor with a wide energy band gap of 3.2 eV, indicating that CeO₂ can only respond to ultraviolet light. In addition, the photocatalytic properties of CeO₂ are predominantly restricted by the rapid recombination of photo-induced electrons and holes. Although a single CeO₂ material exhibits poor photocatalytic performance owing to its low charge-transfer rate, previous investigations indicated that CeO₂ is an excellent cocatalyst with other semiconductors such as Fe₂O₃, Bi₂O₃, CdS, g-C₃N₄, and so on, of the improved charge separation and oxygen reduction at the interfaces between the two coupled catalysts. Ag₃PO₄ is a p-type semiconductor with indirect and direct band gaps are 2.36 eV and 2.43 eV, respectively. On account of that the combination of CeO₂ and Ag₃PO₄ possess well matched overlapping band structure¹⁰¹¹, p-n hetero-junctions could be fabricated by coupling CeO₂ with Ag₃PO₄, which will bring more effective interface transfer of photo-generated electrons and holes to restrain the recombination. Besides, owe to its narrower band gap relative to CeO₂, Ag₃PO₄ is able to act as
efficient photosensitizer to enlarge the light response range under solar light irradiation.

In this paper, we applied a facile process to successfully fabricate Ag₃PO₄/CeO₂ hetero-junctions by an in situ precipitation method. The as-prepared Ag₃PO₄/CeO₂ hetero-junctions demonstrated much higher activity than that of single Ag₃PO₄ or CeO₂ under the irradiation of visible light as well as UV light. Furthermore, the stability of the Ag₃PO₄/CeO₂ photocatalyst was investigated and a photocatalytic mechanism under visible-light irradiation was proposed.

2. Experimental section

2.1. Preparation of CeO₂ nano-particles

All reagents are of analytic grade and used without further purification. In a typical procedure, 1.0 g of cerium nitrate hexahydrate (Ce(NO₃)₃·6H₂O) was fully dissolved in 40 mL formalin solution under vigorous magnetic stirring for 10 min. Afterwards, 1.5 g of sodium hydroxide (NaOH) was added into the above solution and was transferred in to a 50 mL capacity Teflon-lined stainless steel autoclave. Subsequently, the autoclave was laid in an oven at 140 °C for 40 h under autogenous pressure and static conditions. After reaction, the suspension was cooled down to room temperature. The as-obtained powder samples were centrifuged and washed with distilled water, and then dried completely in an oven at 80 °C for 12 h. The dried powders were heated to 450 °C in air at a rate of 5 °C min⁻¹ and calcined for 5 h. The light yellow powders were obtained.

2.2. Preparation of Ag₃PO₄/CeO₂ heterostructure composite

The preparation of the Ag₃PO₄/CeO₂ heterostructure composite was carried out by an in situ precipitation method. In a typical synthesis process, 0.1 g of as-prepared CeO₂ nano-particles were dispersed in 150 mL deionized water and sonicated for 30 min. Immediately after sonication, AgNO₃ aqueous solution (100 mL, 0.012 mol L⁻¹) was added to the white CeO₂ dispersed solution, followed by magnetic stirring. Na₂HPO₄ aqueous solution (200 mL, 0.003 mol L⁻¹) was then added dropwise, accompanied with thorough stirring until the color of the solution changed from white to yellow. The precipitate was centrifuged and washed several times with deionized water and absolute ethanol, and dried at 80 °C for 10 h. For comparison, Ag₃PO₄ particles were also prepared under the same conditions without the presence of CeO₂ nanoparticles.

2.3. Characterization

X-ray powder diffraction (XRD) patterns of the samples were recorded on a Bruke D8 Advance powder X-ray diffractometer with Cu Ka (λ=0.15406 nm) over a range of 10-70° (2θ) with 0.02° per step. A HITACHI S-4800 field emission scanning electron microscope (FE-SEM) was used to characterize the morphologies of the synthesized samples. High resolution transmission electron microscopic (HRTEM) images were acquired with a JOEL JEM 2100 microscope. UV-Vis diffuse reflectance spectra (DRS) of the samples were recorded on a Schimadzu UV 2550 spectrophotometer with an integrating sphere attachment within the range of 200 to 800 nm and with BaSO₄ as the reflectance standard.

2.4. Photocatalytic activity measurements

The photocatalytic activity of the Ag₃PO₄/CeO₂ heterostructures was investigated by the photodegradation of Rhodamine B (RhB, 10 mg/L). Prior to the irradiation, the suspension containing 250 mL of RhB solution and 0.10 g catalysts was magnetically stirred in the dark for 30 min to establish adsorption-desorption equilibrium between the surface of the catalysts and the dye under ambient conditions. A 300 W mercury lamp with a maximum emission at 356 nm was used as the UV source, a 300 W Xe arc lamp as the visible light source where the UV components were filtered out during visible light photocatalysis. The distance between it and the photocatalyst was 50 cm. The light intensity reaching the samples was measured using a radiometer and was found to be approximately 35 W m⁻² in the visible-light range. At varied irradiation time intervals, an aliquot of the mixed solution was collected and centrifuged, and the residual RhB concentration in the supernatant was analyzed by UV-vis spectroscopic measurements (Hitachi UV-3100).

3. Results and discussion

3.1. Morphology and structure characterization of catalyst

Figure 1 illustrates the XRD patterns of the obtained pure CeO₂ nanoparticles, Ag₃PO₄ and Ag₃PO₄/CeO₂ p-n heterojunctions. It is observed that all of the diffraction peaks shown in Figure 1a and b can be indexed to the cubic fluorite-type CeO₂ structure (JCPDS no. 43-1002) and body-centered cubic structure of Ag₃PO₄ (JCPDS no. 06-0505), respectively. The sharp diffraction peaks of both Ag₃PO₄ and CeO₂ indicate their good crystallinity. No traces of other phases are detected, confirming the high purity of the samples. The XRD pattern of the Ag₃PO₄/CeO₂ p-n heterojunctions (Figure 1c) clearly matches with the polycrystalline structures of Ag₃PO₄ (the peak without the triangle mark) and CeO₂ (the peak with

![Figure 1 XRD patterns of (a) CeO₂, (b) Ag₃PO₄ and (c) Ag₃PO₄/CeO₂.](image-url)
the triangle mark), indicating that the Ag$_3$PO$_4$/CeO$_2$ p-n heterojunctions has been successfully prepared.

The morphology of the as-synthesized pure CeO$_2$, Ag$_3$PO$_4$ and the Ag$_3$PO$_4$/CeO$_2$ p-n heterojunctions was examined by FE-SEM, as shown in Figure 2. It can be seen that pure CeO$_2$ (Figure 2a) exhibits spherical-shaped nanoparticles with diameters of about 30 nm, whereas pure Ag$_3$PO$_4$ is about 200–300 nm with a smooth surface (Figure 2b). When CeO$_2$ was deposited on the surface of Ag$_3$PO$_4$ via a facile precipitation-deposition process (Figure 2c-d), the resulting Ag$_3$PO$_4$/CeO$_2$ composite sample exhibits a similar morphology and size as compared to that of pure Ag$_3$PO$_4$. Obviously, the coexistence of CeO$_2$ and Ag$_3$PO$_4$ did not significantly affect their morphology. It is noticeable that the CeO$_2$ nanoparticles are uniformly distributed in the Ag$_3$PO$_4$ crystallites and form a composite structure. To further confirm the crystallographic structure of the Ag$_3$PO$_4$/CeO$_2$ p-n heterojunctions, high-resolution TEM (HRTEM) measurement was carried out (Figure 3). As shown

![Figure 2 FE-SEM images of (a) CeO2, (b) Ag3PO4 and (c-d) Ag3PO4/ CeO2.](image)

![Figure 3 HRTEM images (a-c) of as prepared Ag3PO4/ CeO2 heterojunction.](image)
in Figure 3b, the synthesized $\text{Ag}_3\text{PO}_4/\text{CeO}_2$ composite are of sphere morphology and is composed with inner $\text{Ag}_3\text{PO}_4$ core (Region I) and outer layer (Region II) of $\text{CeO}_2$ nanoparticle. Clear lattice fringes of the small $\text{CeO}_2$ nanocrystals can also be observed in Figure 3c, and inter-planar spacings are measured to be $0.313 \text{ nm}$, which agrees with the $d$ values of the (111) plane of the cubic fluorite-type $\text{CeO}_2$.

### 3.2. UV-Vis absorption spectra

The optical absorption plays an important role in the photocatalysis, especially in the visible-light photodegradation of contaminants. The optical absorption properties of pure $\text{CeO}_2$, $\text{Ag}_3\text{PO}_4$, and the $\text{Ag}_3\text{PO}_4/\text{CeO}_2$ p-n heterojunctions were measured by UV-vis DRS and demonstrated in Figure 4. For pure $\text{CeO}_2$, an adsorption edge can be observed at $420 \text{ nm}$ and can absorb solar energy with a wavelength shorter than $420 \text{ nm}$ (Figure 4a), which is in agreement with the results previously reported $^{10, 11}$. It can be clearly seen that pure yellow $\text{Ag}_3\text{PO}_4$ can absorb energy with wavelengths shorter than $550 \text{ nm}$ (Figure 4b), in agreement with the results previously reported$^{15}$. Upon the loading of the $\text{CeO}_2$ nanoparticles on the surface of $\text{Ag}_3\text{PO}_4$, the absorption edge of heterocrystals was drastically extended to around $560 \text{ nm}$ and the absorption intensity in the region of $200-800 \text{ nm}$ has been evidently increased. The red-shift of the absorption wavelength indicated that the photocatalyst could absorb more photons. Therefore, the red-shift in the absorption band could be favorable for photocatalytic reaction. These results clearly reveal that the in situ deposited of $\text{CeO}_2$ nanoparticles on the crystal surfaces of $\text{Ag}_3\text{PO}_4$ can serve as an effective strategy for enhancing their visible-light absorption.

### 3.3. Photocatalytic activity

#### 3.3.1. Visible light photocatalytic activities of $\text{Ag}_3\text{PO}_4/\text{CeO}_2$

In this study, Rhodamine B (RhB), with a major absorption band at $554 \text{ nm}$, was chosen as a model pollutant for testing photocatalytic activity of the as-prepared products. The absorption spectra of RhB (Figure 5a), with $0.1 \text{ g}$ of the $\text{Ag}_3\text{PO}_4/\text{CeO}_2$ p-n heterojunction photocatalyst under visible light irradiation, clearly show that the characteristic absorption peaks corresponding to RhB decrease rapidly as the exposure time increases, indicating the decomposition of RhB and the significant reduction in the RhB concentration. In this experiment, the photodegradation process is studied by monitoring the change in RhB concentration. The degradation efficiency of RhB over pure $\text{CeO}_2$, $\text{Ag}_3\text{PO}_4$, and the $\text{Ag}_3\text{PO}_4/\text{CeO}_2$ p-n heterojunctions under visible irradiation is presented in Figure 5b. It can be seen that $88.0\%$ of the RhB is photocatalytically degraded after $60 \text{ min}$ irradiation for the $\text{Ag}_3\text{PO}_4/\text{CeO}_2$ composite. For comparison, the activity of the $\text{Ag}_3\text{PO}_4$ and $\text{CeO}_2$ sample for RhB degradation is much...
lower than that of the \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) p-n heterojunctions. For the pure \( \text{Ag}_3\text{PO}_4 \) and \( \text{CeO}_2 \) samples, the RhB is degraded by only 47.0\% and 10\%, respectively.

To quantitatively investigate the reaction kinetics of the RhB degradation, the experimental data were fitted by a first-order model as expressed by the formula\(^{11}\):

\[
-\ln \left( \frac{C}{C_0} \right) = kt
\]

where \( C_0 \) and \( C \) are the dye concentrations in solution at times 0 and \( t \), respectively, and \( k \) is the apparent first-order rate constant.

The kinetic data curves for RhB photocatalytic degradation with photocatalysts in the inset of Figure 5b show that the relationship between \( \ln \left( C/C_0 \right) \) and irradiation time is almost linear, suggesting that the photocatalytic reaction follows pseudo-first-order kinetics. As can be seen in Figure 5b, the pseudo-first-order rate constants \( (k) \) for RhB degradation with \( \text{CeO}_2 \), \( \text{Ag}_3\text{PO}_4 \) and \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) composite were estimated to be 0.0004 min\(^{-1}\), 0.0082 min\(^{-1}\), 0.0331 min\(^{-1}\), respectively. The rate constant of the \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) composite is 82.8 times as high as that of \( \text{CeO}_2 \) and 4.0 times as that of \( \text{Ag}_3\text{PO}_4 \). The results demonstrate that the degradation efficiency of the \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) composite to RhB in much higher than those of pure \( \text{Ag}_3\text{PO}_4 \) and \( \text{CeO}_2 \) under visible light irradiation.

To elucidate the photocatalytic reaction mechanism, the main species including \( h^+ \), \( \cdot \text{O}_2^- \) and \( \cdot \text{OH} \) involved in the photocatalytic process was examined. The method was applied according to the Xiang’s report without any modification\(^{16}\). The results indicated that \( h^+ \) and \( \cdot \text{O}_2^- \) were the main reactive oxidizing species in photocatalytic reaction process of \( \text{Ag}_3\text{PO}_4/\text{Ag} \) composites.

3.3.2. UV light photocatalytic activities of \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \)

Although \( \text{CeO}_2 \) has poor capacity for RhB degradation under visible light irradiation due to its higher band gap energy, it shows high photocatalytic capability in the UV region\(^{17,18}\). To investigate the effect of the coupling \( \text{Ag}_3\text{PO}_4 \) sensitizer on the photocatalytic capability of \( \text{CeO}_2 \), the photocatalytic degradation of RhB over \( \text{CeO}_2 \), \( \text{Ag}_3\text{PO}_4 \) and the \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) p-n heterojunction under 300 W UV irradiation has also been performed. As shown in Figure 6, \( \text{CeO}_2 \) and \( \text{Ag}_3\text{PO}_4 \) show only 35\% and 86\% RhB degradation, whereas the \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) composite renders 98.3\% RhB degradation after 10 min of photocatalytic reaction. The \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) composite exhibits the highest photocatalytic degradation efficiency, followed by the pure \( \text{Ag}_3\text{PO}_4 \) and \( \text{CeO}_2 \) photocatalysts. Additionally, pseudo-first-order rate constants \( (k) \) for RhB decomposition by the \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) composite under UV light irradiation is about 0.2262 min\(^{-1}\), faster than that with \( \text{Ag}_3\text{PO}_4 \) (0.0909 min\(^{-1}\)) and pure \( \text{CeO}_2 \) (0.0205 min\(^{-1}\)) by a factor of 2.5 and 11.0, respectively. The results demonstrate that the degradation efficiency of the \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) composite to RhB in much higher than those of pure \( \text{Ag}_3\text{PO}_4 \) and \( \text{CeO}_2 \) under UV light irradiation.

3.3.3. Photocatalytic stability

In addition to photocatalytic efficiency, the stability of photocatalyst is also very important for practical application. To evaluate the stability of the photocatalytic performance of \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) composite, the circulating run in the photocatalytic degradation of RhB was carried out under visible light irradiation. As shown in Figure 7, the photocatalytic degradation efficiency of RhB still reached 82\% after 3 cycles in 3 h. The decrease of degradation efficiency under the third run may be due to the loss of sample during the cycling reaction. Furthermore, the XRD analysis of \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) photocatalyst before and after photocatalytic reaction indicated no difference between the two lines. The result demonstrates that the \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) composite, formed by the coupling of \( \text{CeO}_2 \) and \( \text{Ag}_3\text{PO}_4 \), shows excellent photocatalytic performance, as well as good stability.

3.4. Photocatalytic mechanism of \( \text{Ag}_3\text{PO}_4/\text{CeO}_2 \) heterojunctions

Based on the above results, it is evident that the enhanced activity of the hybrid photocatalyst involving \( \text{CeO}_2 \) nanoparticles and \( \text{Ag}_3\text{PO}_4 \) can be attributed to the synergistic effects
of visible-light sensitization and p-n junction structure\textsuperscript{19}. \(\text{Ag}_3\text{PO}_4\) is a typical p-type semiconductor with a narrow band gap\textsuperscript{11} while \(\text{CeO}_2\) is an n-type semiconductor with a large band gap\textsuperscript{20}. In order to fully understand the energy band structure of the p-\(\text{Ag}_3\text{PO}_4\)/n-\(\text{CeO}_2\) heterojunction, the original energy band structures of \(\text{Ag}_3\text{PO}_4\) and \(\text{CeO}_2\) were provided. The valence band edge positions of \(\text{Ag}_3\text{PO}_4\) and \(\text{CeO}_2\) were estimated in this study according to the concept of electronegativity\textsuperscript{18}. The conduction band (CB) and valence band (VB) positions of the two semiconductors at the point of zero charge are predicted theoretically by the following empirical equations\textsuperscript{21}:

\[
E_{\text{VB}} = X - E' + 0.5 E_g
\]

\[
E_{\text{CB}} = E_{\text{VB}} - E_g
\]

where \(E'_{\text{CB}}\) is the valence band (CB) potential; \(E_{\text{VB}}\) is the conduction band (VB) potential; \(X\) is the absolute electronegativity of the semiconductor, which is defined as the geometric mean of the absolute electronegativity of the constituent atoms; \(E'\) is the energy of free electrons on the hydrogen scale (ca. 4.5 eV); and \(E_g\) is the band gap of the semiconductor. The conduction band (CB) position can be deduced by eqn (2). The \(X\) values for \(\text{Ag}_3\text{PO}_4\) and \(\text{CeO}_2\) are ca. 5.959 and 5.696 eV, respectively. The band-gap energies of \(\text{Ag}_3\text{PO}_4\) and \(\text{CeO}_2\), in our experiment, are estimated to be 2.32 and 2.86 eV, respectively. Herein, based on eqn (1) and (2), the top of the VB and the bottom of the CB for \(\text{Ag}_3\text{PO}_4\) are calculated to be 2.619 and 0.299 eV respectively. Accordingly, the VB and CB of \(\text{CeO}_2\) are estimated to be 2.626 and -0.234 eV, respectively. The energy band structure diagram of p-type \(\text{Ag}_3\text{PO}_4\) and n-type \(\text{CeO}_2\) is thus schematically illustrated in Figure 8a.

When p-type \(\text{Ag}_3\text{PO}_4\) and n-type \(\text{CeO}_2\) are in contact, the Fermi level of \(\text{Ag}_3\text{PO}_4\) is raised up, while the Fermi level of \(\text{CeO}_2\) is lowered until an equilibrium state is formed as shown in Figure 8b. Meanwhile, with the raising up and/or lowering of the Fermi level, the energy bands of \(\text{Ag}_3\text{PO}_4\) shift upward along the Fermi level \(E_{\text{fp}}\) and those of the \(\text{CeO}_2\) shift downward along its Fermi level \(E_{\text{fn}}\), and as a result, the conduction band edge of p-type \(\text{Ag}_3\text{PO}_4\) is higher than that of n-type \(\text{CeO}_2\), leading to the formation of a p-n junction at the interface between \(\text{Ag}_3\text{PO}_4\) and \(\text{CeO}_2\) crystals. Thus, at the thermodynamic equilibrium, an inner electric field orienting from \(\text{CeO}_2\) to \(\text{Ag}_3\text{PO}_4\) was established in the interface between \(\text{CeO}_2\) and \(\text{Ag}_3\text{PO}_4\).

Therefore, we speculated a photocatalytic mechanism of the p-\(\text{Ag}_3\text{PO}_4\)/n-\(\text{CeO}_2\) heterojunction as follows: under visible light illumination, \(\text{Ag}_3\text{PO}_4\) acting as a photosensitizer could be easily activated by visible light and generated electrons and holes. From Figure 8b, it can be found that under the function of an internal electric field, the electrons from the excited \(\text{Ag}_3\text{PO}_4\) transfer to the conduction band of \(\text{CeO}_2\), and simultaneous holes remain in the p-\(\text{Ag}_3\text{PO}_4\) valence band. In such a way, the photogenerated electron-hole pairs will be separated effectively by the p-n junction formed in the heterostructured p-\(\text{Ag}_3\text{PO}_4\)/n-\(\text{CeO}_2\) interface and the photocatalytic activity is much enhanced. That is to say, to some extent, the recombination of photogenerated electrons and holes can be restrained. Furthermore, the migration rates of the photogenerated electrons and holes are promoted by the internal electric field in the p-n heterojunctions. The efficient charge separation could increase the lifetime of the charge carriers and has enough time to react with the reactants adsorbed onto the photocatalyst surfaces so as to improve the photocatalytic activity. According to the above results and discussion, it is apparent that the synergetic effects of the p-n junction formed between \(\text{Ag}_3\text{PO}_4\) and \(\text{CeO}_2\) were responsible for the enhanced visible-light photocatalytic activity.

![Figure 8 Schematic diagrams for (a) energy bands of p-Ag3PO4 and n-CeO2 before contact and (b) the formation a p-n junction and its energy band diagram at equilibrium and transfer of photoinduced electrons form p-Ag3PO4 and n-CeO2 under visible-light irradiation.](image-url)
4. Conclusions

In summary, we have successfully fabricated Ag$_2$PO$_4$/CeO$_2$ p-n heterojunctions by depositing small CeO$_2$ nanoparticles sized of 10-15 nm on the surface of Ag$_2$PO$_4$ via a facile precipitation route. The obtained Ag$_2$PO$_4$/CeO$_2$ p-n heterojunctions exhibited enhanced photocatalytic activity toward RhB degradation under ultra-violet and light irradiation than that of pure Ag$_2$PO$_4$ and CeO$_2$ nanoparticles. Such enhanced photocatalytic activity of the Ag$_2$PO$_4$/CeO$_2$ p-n heterojunctions could be attributed to high dispersibility of small CeO$_2$ nanoparticles, broadened of the optical absorption range as well as the generation of a p-n junction between p-type Ag$_2$PO$_4$ and n-type CeO$_2$. This work not only supports the possibility of using cost-effective n-type CeO$_2$ for photocatalytic degradation organic dye but also shows that a suitable p-n junction structure is crucial for high photocatalytic activity in a hybrid photocatalyst.
