In this paper we report the effect of alloying elements on hydrogen storage properties of melt-spun Mg-based alloys. The base alloys Mg₉₀Si₁₀, Mg₆₅Cu₁₅, Mg₆₅Cu₁₀ (at%) were studied. We also investigated the effect of rare earths (using MM: mischmetal) and Al in Mg₆₅Cu₁₅Al₁₀, Mg₆₅Cu₁₅MM₁₀ and Mg₆₅Cu₁₅Al₁₅MM₁₀ alloys. All the melt-spun alloys without MM show a crystalline structure, and the Mg₆₅Cu₁₅MM₁₀ and Mg₆₅Cu₁₅Al₁₅MM₁₀ alloys showed an amorphous and partially amorphous structure respectively. At 350°C all the alloys had a crystalline structure during the hydrogen absorption-desorption tests. It was observed that Si and Cu in the binaries alloys hindered completely the activation of the hydrogen absorption. The partial substitution of Cu by MM or Al allowed activation. The combined substitution of Cu by MM and Al showed the best results with the fastest absorption and desorption kinetics, which suggests that this combination can be used for new Mg-alloys to improve hydrogen storage properties.

Keywords: Hydrogen storage, Mg based alloy, Rapid solidification, Nanomaterials

1. Introduction

Hydrogen is a promising clean energy carrier with great potential for mobile and stationary applications replacing petroleum fuels1. There are many technological and economic problems to be solved to extend industrial applications of hydrogen as fuel: the production, storage and energy conversion systems. Hydrogen storage is clearly one of the key challenges in developing hydrogen economy. Three basic hydrogen storage methods are considered, which at the present are: (i) pressurized gas, (ii) cryogenic liquid, (iii) solid fuel as chemical or physical combination with materials, such as metal hydrides and complex hydrides2.

Each of these options possesses attractive attributes for hydrogen storage3. Mg-base alloys have great potential for solid-state hydrogen storage, because Mg has high hydrogen absorption capacity near to 7.6 wt% H for MgH₂, more than most other metal hydrides, good reversibility, low specific weight, low cost and a comparatively high availability in the earth’s crust1,4. First works in this area were made by Reilly and Wiswall6,6 on Mg-Cu-H and Mg-Ni-H systems. However, the hydrogen absorption-desorption kinetics are slow and need high temperature (from 300°C to 400°C) due to the large formation enthalpy of the Mg hydride and diffusion properties. Possible ways to improve the hydrogen absorption-desorption kinetics are alloying Mg to modify the crystal structure of the hydrides by addition of transition metals, metal oxides or rare earths7–15, reducing the grain size by alloying elements, mechanical deformation or rapid solidification. In recent years the absorption-desorption of hydrogen in Mg alloys produced by unconventional methods have been investigated16–18. It was observed that the reaction kinetics are improved when the Mg based materials have nanometric structures19,20. The addition of rare earths increases the kinetics of absorption and/or desorption in Mg-Ni and Mg-Cu-Ni alloys21,22. It was also observed that absorption-desorption kinetics are favorable in Mg-Al alloys containing amorphous or nanostructured phases when it is compared to pure Mg23. In general, absorption-desorption kinetics of alloys with amorphous phases and/or nano-crystalline microstructure are higher at lower temperature when compared to micro-crystalline structures24.

Amorphous and/or nano-structured Mg alloys can be achieved by rapid solidification or mechanical grinding processes. In general, in these alloys the crystallization
temperature of the amorphous phase is lower than the activation temperature of the hydrogen absorption-desorption processes with reasonable rate, thus the amorphous phase has the effect of generating nanostructured alloys by crystallization. Alloys with nano-crystalline phases or a microstructure composed of nano-crystalline and amorphous phases exhibit higher rate of absorption-desorption kinetics at lower temperature in comparison with microcrystalline materials of the same composition.

The aim of the present work is to study the effect of alloying elements of Mg on the hydrogen absorption-desorption behavior in different alloys produced by melt spinning, as described in the Table 1. The effect of Cu and Si were studied in the Mg<sub>65</sub>Cu<sub>10</sub>, Mg<sub>65</sub>Cu<sub>15</sub> and Mg<sub>65</sub>Si<sub>10</sub> (at%) alloys. The effect of Al and rare earths (using MM: mischmetal) were studied in the Mg<sub>65</sub>Cu<sub>10</sub>Al<sub>10</sub>, Mg<sub>65</sub>Cu<sub>10</sub>MM<sub>10</sub> and Mg<sub>65</sub>Cu<sub>10</sub>Al<sub>15</sub>MM<sub>10</sub> alloys. The Mg<sub>65</sub>Cu<sub>10</sub>MM<sub>15</sub> alloy can be obtained in amorphous state by rapid solidification. It is known that the addition of Al to pure Mg destabilizes the MgH<sub>2</sub> and forms Mg/Al alloys upon dehydrogenation. The MgSi phase is also attractive as a hydrogen storage material due to favorable desorption enthalpy (ΔH<sub>desorption</sub> ≈ 36 kJ/mol H<sub>2</sub>) for room temperature operation.

2. Experimental

Master alloy ingots with the chemical compositions Mg<sub>65</sub>Cu<sub>10</sub>MM<sub>15</sub> and Mg<sub>65</sub>Cu<sub>10</sub>Al<sub>15</sub>MM<sub>15</sub> were produced from pure elements by diffusion of filed Cu particles in a Mg-MM or Mg-MM-Al molten alloy in a graphite crucible under Argon atmosphere in an electric furnace at 950°C. The other master alloys were prepared by melting of pure elements in an induction furnace in a graphite crucible under argon atmosphere.

Melt spun samples were prepared under Argon atmosphere using a BN coated quartz tube. Continuous ribbons with 20-35 µm in thickness and ~1 mm in width were obtained for MM containing alloys. Melt spun samples of the other alloys were obtained with thickness between 80-100 µm and ~4 mm in width.

The characterization of the morphology of the melt spun samples has been carried out using a JEOl 6510 LV scanning electron microscope (SEM). The atomic structure of the as-spun and hydrogenated samples was characterized by X-ray diffraction using Cu-Kα radiation. The thermal stability and the crystallization process of the melt-spin samples were studied by differential scanning calorimetry (DSC) at a heating rate of 20 K/min under Argon flow. A complementary heat treatment at 360°C was performed to analyse the phases in a complete crystallized state.

Hydrogen absorption-desorption tests were performed on the as-spun samples in a home-made Sieverts apparatus at 350°C and 2000 kPa for the absorption and 150 kPa for desorption. Both temperature and pressures used are the usual working parameters for pure Mg and many of its alloys.

For the tests, each sample was carefully weighed and then inserted in a sample holder, fixing the holder onto the device and purging the whole system with three cycles of 120 kPa hydrogen/vacuum. After this it was ready to start the tests. Under vacuum, the sample was isolated from the system and heated up to its operating temperature. When the sample reached the required temperature and maintaining the sample isolated, hydrogen was entered automatically in the system. Once at the set pressure, it was open the sample isolation valve and proceeded to record data.

3. Results and discussion

The surface of all ribbons (facing wheel and facing air) had typical morphologic features of samples produced by melt spinning. Figure 1(a) shows a secondary electrons (SE) image of facing wheel Mg<sub>65</sub>Cu<sub>10</sub> ribbon where traces of roughness of the copper wheel and from bubbles trapped between the liquid and the copper wheel during the solidification process could be seen. Figure 1(b) shows a backscattered electrons (BSE) image of a cross section of the Mg<sub>65</sub>Cu<sub>10</sub> as-spun sample where a dendritic morphology can be observed. Figure 1(c) and (d) show SE images of the Mg<sub>65</sub>Si<sub>10</sub> as-spun sample, where in (c) typical ripples of the facing wheel of a melt spun sample are present; and in (d) an equiaxed grain structure on the surface facing the air can be observed.

Figures 2(a), (b), (c) and (d), show the X-ray diffractograms of the alloys Mg<sub>65</sub>Cu<sub>10</sub>, Mg<sub>65</sub>Cu<sub>15</sub>, Mg<sub>65</sub>Si<sub>10</sub> and Mg<sub>65</sub>Cu<sub>10</sub>Al<sub>10</sub> in the as-spun state and after hydrogen absorption-desorption cycles, respectively. In the binary Mg-Cu alloys only stable equilibrium phases are observed in both states; Mg and MgCu<sub>2</sub> for Mg<sub>65</sub>Cu<sub>15</sub> and MgCu<sub>2</sub>Al<sub>10</sub> for Mg<sub>65</sub>Cu<sub>10</sub>Al<sub>10</sub> alloy. In the Mg<sub>65</sub>Si<sub>10</sub> alloy, also the stable phases are observed, Mg and MgSi; in addition traces of the silicon oxide, SiO<sub>2</sub> can be observed. The diffractograms of the ternary alloy Mg<sub>65</sub>Cu<sub>2</sub>Al<sub>10</sub>, show the presence of the Mg and (Cu,Al)<sub>2</sub>Mg phases. No peaks related to hydrides and no new phases were observed in the diffractograms after the hydrogen absorption-desorption cycle for Mg<sub>65</sub>Cu<sub>10</sub>, Mg<sub>65</sub>Cu<sub>15</sub> and Mg<sub>65</sub>Cu<sub>10</sub>Al<sub>10</sub> alloys.

Figures 3(a) and (b) show the X-ray diffractograms of Mg<sub>65</sub>Cu<sub>10</sub>MM<sub>10</sub> and Mg<sub>65</sub>Cu<sub>10</sub>Al<sub>15</sub>MM<sub>10</sub> alloys in the as-spun state, after three cycles of hydrogen absorption-desorption and of the heat treated sample in a constant heating up to 360°C.

The as-spun Mg<sub>65</sub>Cu<sub>10</sub>MM<sub>10</sub> sample shows a typical X-ray diffractogram of an amorphous structure with a broad peak at 20 ~35.7°. The X-ray diffractograms after three cycles of hydrogen absorption-desorption show the MgCu<sub>2</sub>, MgH<sub>2</sub>, MgCuMM phases. However, some peaks in the diffractograms could not be identified. The indexed phases after the heat treatment correspond to MgCu and MgCuMM phases and the un-identified peaks present in the diffractogram after
Figure 1: SEM micrographs of as-spun samples. (a) SE image facing wheel of the Mg$_{90}$Cu$_{10}$ sample; (b) BSE image of a cross section of the Mg$_{90}$Cu$_{10}$ sample; (c) SE facing wheel of the Mg$_{90}$Si$_{10}$ sample; (d) SE facing air of the Mg$_{90}$Si$_{10}$ sample.

Figure 2: X-ray diffractograms of the as-spun samples and after hydrogen absorption-desorption cycles of the alloys: (a) Mg$_{90}$Cu$_{10}$, (b) Mg$_{65}$Cu$_{35}$, (c) Mg$_{90}$Si$_{10}$ and (d) Mg$_{65}$Cu$_{25}$Al$_{10}$. 
hydrogen absorption-desorption cycles are not present, which suggests those could correspond to an hydride.

In the as-spun $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$ sample the X-ray diffractogram shows a broad peak at 20 = 34.7º and some other peaks that could be indexed as corresponding to the $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$ phase. The microstructure at the as-spun state of this alloy would be composed of $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$ nanocrystals embedded in an amorphous matrix. These results suggest that the substitution of 15at% Cu by Al reduces the glass forming ability of the $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$ alloy. The identified phases in the X-ray diffractogram of the Mg-Cu-Al-MM sample after three cycles of hydrogen absorption-desorption are Mg, $\text{Mg}_{17}$, $(\text{Cu,Al})_2\text{Mg}_3$, and MgH$_2$. Also few peaks could not be identified, which are in the same 20 position as observed before for the $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$ alloy. After the heat treatment up to 360ºC of the as-spun sample the indexed phases in X-ray diffractogram are Mg$_2$Cu, $(\text{Cu,Al})_2\text{Mg}_3$, and Mg$_2$MM$_2$ phases, and the un-identified peaks present in the diffractogram after hydrogen absorption-desorption cycles are not present, which again suggests those could correspond to an hydride remained in the cycled sample.

Figures 4(a) and (b) show DSC curves of as-spun amorphous $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$ and partially amorphous $\text{Mg}_{65}\text{Cu}_{25}\text{Al}_{15}\text{MM}_{10}$ samples. During heating the crystallization process consists of several steps for both alloys.

The crystallization process of the $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$ occurs in three steps. A first sharp exothermic peak at $T_p$ ~ 170ºC is followed by a second step with overlapped peaks that have an average peak temperature at $T_p$ ~ 205ºC. Finally, the crystallization process ends with a third step with a sharp exothermic peak at $T_p$ ~ 261ºC. The temperature of the first exothermic peak is ~13ºC lower than that obtained in the work of Murty et al.25, which is reasonable considering they used a higher heating speed (40ºC/min) than in our work (20ºC/min).

On the other hand, the crystallization process in the partially amorphous $\text{Mg}_{65}\text{Cu}_{25}\text{Al}_{15}\text{MM}_{10}$ alloy occurs in two exothermic steps with a first broad asymmetric peak at $T_p$ ~ 194ºC and a second sharp peak at $T_p$ ~ 305ºC. The remained amorphous phase in the $\text{Mg}_{65}\text{Cu}_{25}\text{Al}_{15}\text{MM}_{10}$ is stable at higher temperature than the amorphous phase in the alloy without Al, moreover the end of the crystallization process is shifted at higher temperature, few degrees below the test temperature (350ºC) used for the hydrogen absorption-desorption cycles. Thus, the Al-containing alloy could develop a microstructure with a smaller grain size at 350ºC during hydrogen cycles than the $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$.

The DSC curves obtained for the as-spun crystalline samples, Mg-Cu, Mg-Si and Mg-Cu-Al alloys, did not showed any peak (solid state transformations), and are not showed in this work.

Figure 5 shows the hydrogen absorption curves of the $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$, $\text{Mg}_{65}\text{Cu}_{25}\text{Al}_{15}\text{MM}_{10}$ and $\text{Mg}_{65}\text{Cu}_{25}\text{Al}_{15}\text{MM}_{10}$ alloys. The binary alloys present an inert behaviour under hydrogenated atmosphere, doesn’t show capacity for the absorbing reaction and hydrides formation at 350ºC and 2000 kPa. However, the partial substitution of 10at%Cu by Al (ternary alloy $\text{Mg}_{65}\text{Cu}_{25}\text{Al}_{15}\text{MM}_{10}$) shows a low hydrogen absorption capacity (~1 wt%H after 2hrs 15min). The low absorption rate could correspond to: a low fraction of free Mg in the alloy to form hydride and/or some barrier in the sample surface that prevents the diffusion of hydrogen into the volume of the sample. Krozer et al. and Luz et al.29,30 explain this phenomenon due to a dense surface layer of hydrides which do not allow the diffusion of hydrogen in the sample. Figures 6(a), (b) and (c) show the activation, second and third cycle of hydrogen absorption for the $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$ and $\text{Mg}_{65}\text{Cu}_{25}\text{Al}_{15}\text{MM}_{10}$ alloys respectively. These alloys were tested to three consecutive cycles of hydrogen absorption-desorption. It was found that the rate of the first absorption cycle (activation) is low, which is usual for Mg alloys31. The sluggish rate during the activation cycle can be related to the presence of an oxide layer on the surface of the sample, which must be broken to start the hydrogenation through the volume of the material4. The Al-containing alloy shows a harder activation process than the $\text{Mg}_{65}\text{Cu}_{25}\text{MM}_{10}$ alloy; however, once the hydrogenation is activated the absorption
Effect of Alloying Elements in Melt Spun Mg-alloys for Hydrogen Storage

Figure 4: DSC curves of the as-spun Mg₆₅Cu₂₅M₅ and Mg₆₅Cu₁₀Al₁₅M₅ samples.

Figure 5: Absorption kinetics at 350°C and 2000 kPa of Mg₉₀Cu₁₀, Mg₆₅Cu₃₅, Mg₉₀Si₁₀ and the Mg₆₅Cu₂₅Al₁₀ samples.

rate and capacities in the second and third cycles are higher than in the Mg₆₅Cu₂₅M₅ alloy. Thus, the absorption time to reach the hydrogen saturation in the second and third cycle for Mg₆₅Cu₁₀Al₁₅M₅ alloy is lower than for the Mg₆₅Cu₂₅M₅ alloy. The absorption time is observed to decrease from the second to the third cycle for both alloys, which is in agreement with a general behaviour of H-sorption properties in Mg alloys.  

The partial substitution of Cu by Al in the Mg₆₅Cu₂₅M₅ alloy appears to enhance the kinetic of the hydrogen absorption at 350°C and 2000 kPa.

The hydrogen desorption behavior of Mg₆₅Cu₂₅M₅ and Mg₆₅Cu₁₀Al₁₅M₅ alloys can be analyzed from the curves shown in Figure 7. No incubation time is observed for hydrogen desorption at 350°C and 150 kPa. The desorption rate is faster than the absorption rate for both alloys. There is also observed that the desorption time for the Al-containing alloy during the second cycle is ~100 s while this time is ~600 s for the Mg₆₅Cu₂₅M₅ alloy, both times are shorter than for the first cycle. Then, the desorption time is further reduced for the third cycle. This behavior is in agreement with what was observed by other authors; the presence of Al destabilizes Mg hydrides and consequently increases

Figure 6: Absorption kinetic at 350°C and 2000kPa of the Mg₆₅Cu₂₅M₅ and Mg₆₅Cu₁₀Al₁₅M₅ alloy; (a) first cycle (activation); (b) second cycle, and (c) third cycle.
This shows that the Al addition also improves the reversibility of the Mg$_{65}$Cu$_{25}$MM$_{10}$ alloy. This behaviour can be explained taking into account that Al destabilizes the MgH$_2$ increasing the amount of reversible hydrides.

Considering that an alloy absorbs two hydrogen atoms like MgH$_2$ per each Mg atom in the alloy, from the atomic mass of each composition it can obtain a maximum theoretical hydrogen storage capacity. For Mg$_{65}$Cu$_{25}$MM$_{10}$ and Mg$_{65}$Cu$_{10}$Al$_{15}$MM$_{10}$ alloys these values are 4.2 wt%H and 4.6 wt%H respectively. For the studied samples, it is observed from Figure 6 that in the second cycle the capacities are 2.3 wt%H for Mg$_{65}$Cu$_{25}$MM$_{10}$ and 2.6 wt%H for Mg$_{65}$Cu$_{10}$Al$_{15}$MM$_{10}$; while for the third cycle these values are 1.4 wt%H and 2.2 wt%H respectively.

The partial substitution of Cu by MM or/and by Al in Mg$_{65}$Cu$_{35}$ alloy promotes the formation of hydrides and improve the H-sorption properties of the Mg$_{65}$Cu$_{35}$ alloy as shown in Figure 3, 6 and 7. The X-ray diffractograms of both Mg$_{65}$Cu$_{25}$MM$_{10}$ and Mg$_{65}$Cu$_{10}$Al$_{15}$MM$_{10}$ alloys after the third hydrogenation-dehydrogenation cycle confirm the formation of α-hydride MgH$_2$.

Finally, it is observed that the simultaneous partial substitution of Cu by both Al and MM in the Mg$_{65}$Cu$_{35}$ alloy produced by rapid solidification yields an excellent improvement in the H-sorption properties.

4. Conclusion

From the hydrogen absorption and desorption tests carried out at 350°C and 2000 kPa and at 350°C and 150 kPa respectively, the following effects were demonstrated:
- Cu and Si reduce the hydrogen absorption capacity of Mg in the Mg$_{90}$Si$_{10}$, Mg$_{90}$Cu$_{10}$ and Mg$_{65}$Cu$_{35}$ alloys;
- The partial substitution of 10% Cu by Al in the Mg$_{65}$Cu$_{35}$ improves the hydrogen activation; while the partial substitution of 10% Cu by MM has stronger effect on activation;
- Finally the alloy containing MM and Al, Mg$_{65}$Cu$_{10}$Al$_{15}$MM$_{10}$, has the best behaviour for hydrogen absorption-desorption process. This alloy has higher absorption-desorption kinetic reactions and better reversibility than both ternary alloys, Mg$_{65}$Cu$_{25}$Al$_{10}$ and Mg$_{65}$Cu$_{25}$MM$_{10}$;
- The addition of Rare Earths and Al together in Mg base alloys can be used to design new Mg alloys with improved hydrogen absorption-desorption kinetics and reversibility.

5. Acknowledgments

This work was partially funded by the PICT-Oxford 2010/2831 and the UBACYT 2014/20020130100663. The authors thank Dr. Daniel Vega for taken some of the X-ray diffractograms used in this work.
