Porous Ti/HA nano-composite was prepared for implant fixtures and in situ formation of Hydroxyapatite. At first, Ca(OH)₂ nanoparticles were synthesized by precipitation. Raw materials included Ca(NO₃)₂·4H₂O, NaOH, a mixture of deionized water and ethanol. Synthesized Ca(OH)₂ nano powder was mixed with (NH₄)₂HPO₄ and the mixture was calcined at 700 °C for 30 min. After calcination, Ca₃(PO₄)₂ and CaPO₄(OH)·2H₂O were synthesized with imperfect hexagonal morphology. The resulting powder was mixed with pure titanium powder and pressed under 300, 500 and 700 MPa. The samples were sintered at 1000 °C for an hour under pure argon. Final composition was Ti/HA with hexagonal morphology. XRD and SEM showed the in situ formation of nano hydroxyapatite besides titanium phases during the sintering procedure. The density and open porosity of the 700 MPa pressed-samples were 3.07 g/cm³ and 28.2%, respectively. In general, porous Ti/HA nano-composite with suitable porosity could be successfully synthesized by co-precipitation procedure.

Keywords: Hydroxyapatite, Titanium, In situ synthesis, Calcium hydroxide, Nano-composite.

1. Introduction

Calcium hydroxide, a mineral with chemical formula of Ca(OH)₂, has many applications in chemical substances, industries, environments, medications, and constructions. One of the most important applications of Ca(OH)₂ is to use it as raw material for synthesis of hydroxyapatite. Hydroxyapatite, with chemical formula of Ca₁₀(PO₄)₆(OH)₂, is a ceramic substance. HA is broadly used in medicine and oral biology due to the apatite-like structure of enamel, dentine and human bones. So, it exhibits biological affinity to nearest host tissues in the body and has a great compatibility with body. Thus, it can be used as a basic implant raw material.

2. Literature Review

Bouyer et al. was the first one who introduced synthesis of hydroxyapatite using Ca(OH)₂. In their study, Ca(OH)₂ and ortho-phosphoric acid (H₃PO₄) react according to reaction (1). This reaction leads to formation of hydroxyapatite:

\[ 10Ca(OH)_2 + 6H_3PO_4 \rightarrow Ca_{10}[(PO_4)_6(OH)_2] + 18H_2O \]  

(1)

Santos et al. chose ammonium hydrogen phosphate [(NH₄)₃HPO₄] and calcium hydroxide as raw materials. According to reaction (2), these two substances react and produce hydroxyapatite.

\[ 10 Ca(OH)_2 + 6(NH_4)_2HPO_4 \rightarrow Ca_{10}[(PO_4)_6(OH)_2] + 18H_2O + 12NH_4OH \]  

(2)

Also, they selected calcium hydrogen phosphate [Ca(H₂PO₄)₂·H₂O] and Ca(OH)₂ as the raw materials, to achieve hydroxyapatite, according to reaction (3):

\[ 7Ca(OH)_2 + 3Ca(H_2PO_4)_2·H_2O \rightarrow Ca_{10}[(PO_4)_6(OH)_2] + 15H_2O \]  

(3)

Another way to synthesize hydroxyapatite material is to apply a milling system. Alqap et al. chose (NH₄)₃HPO₄ and calcium hydroxide as raw materials. Since hydroxyapatite has poor mechanical properties in applications such as dental implants, metallic titanium has been added to produce a composite with excellent mechanical and biological properties that can endure forces to jawbone. Thian et al. used powder injection metallurgy to produce Ti/HA composite. They prepared Ti6Al4V and hydroxyapatite powder with poly vinyl alcohol as a binder in slurry form, and mixed them for a specific time.

Karanjai et al. produced titanium based biocomposite with in situ formation of tricalcium-phosphate using powder metallurgy. They used titanium hydride and different ratios of calcium-phosphate compounds which contains calcium carbonate and dianmonium hydrogen phosphate. After sintering, in situ formation of hydroxyapatite, calcium titanite, and tricalcium phosphate phases were observed.

In addition to high strength, a dental implant should be a porous surface-structured design. Although, the porous structure of the implant reduces the Young's modulus, it increases the rate of osteointegration. Moreover, feature of porous structure plays an important role in bone reconstruction due to the link between cavities which causes...
the flow of blood and ions into the structure and encourages the osteointegration. There is no standard for size of the porosities so, pore size can be determined regarding to the required mechanical properties. To have a porous dental implant, powder metallurgy method can be used. In this method, by controlling particle size, compaction pressure, and sintering temperature, pore size can be controlled\textsuperscript{11}.

If the precursor raw materials for hydroxyapatite formation are in nanometer sizes, they can react faster and at a lower temperature. It can produce nano scale size hydroxyapatite material due to high surface area of reactants\textsuperscript{12}.

Webster et al.\textsuperscript{13}, reported that nano structured materials, the grain size of less than 100 nm, increase the adhesion of osteoblast and improve bone growth and amendment. Also, making Ti/HA composite in nano scale has benefits such as increased in hardness, Young’s modulus, and corrosion resistance.

In this project, nano scale precursors were synthesized (i.e. Ca(OH)\textsubscript{2}) and applied to manufacture dental implants. The main objective of the present study was to prepare porous Ti/HA nano-composite for implant fixtures and in situ formation of Hydroxyapatite during powder metallurgy processing.

### 3. Experimental Procedures

In the first step, Ca(OH)\textsubscript{2} was synthesized by using hydrated calcium nitrate powder \([\text{Ca(NO}_3\text{)}_2\cdot 4\text{H}_2\text{O}]\) (Ghatran Shimi, 99%), sodium hydroxide powder (NaOH) (Merck, 99.9%), and ethanol as raw materials. Ca(OH)\textsubscript{2} was precipitated according to reaction (4).

\begin{equation}
\text{Ca(NO}_3\text{)}_2\cdot 4\text{H}_2\text{O} + 2\text{NaOH} \rightarrow
2\text{NaNO}_3 + \text{Ca(OH)}_2 + 4\text{H}_2\text{O}
\end{equation}

(4)

After synthesis and characterization of nano Ca(OH)\textsubscript{2}, this powder was mixed with \((\text{NH}_4\text{)}_2\text{HPO}_4\) (DAP) and milled in a mortar for 10 min. Then, the mixture was screened by a 120 micrometer sieve and was calcined to prepare hydroxyapatite, according to reaction (5).

\begin{equation}
5\text{Ca(OH)}_2 + 3\text{(NH}_4\text{)}_2\text{HPO}_4 \rightarrow
\text{Ca}_5\text{(PO}_4\text{)}_3\text{OH} + 9\text{H}_2\text{O} + 6\text{NH}_3
\end{equation}

(5)

Calcination temperature was selected on the decomposition temperature of the raw materials. The mixture of powder was heated to 250 °C and held at this temperature for 30 minutes to complete decomposition of \((\text{NH}_4\text{)}_2\text{HPO}_4\), then the temperature increased to 700 °C and kept for 30 minutes to form calcium phosphates of biological interest, and then cooled down slowly.

After calcination, the mixture of powder was again mixed with pure titanium powder (with the aspect of 1:4 ratio) and screened to have a homogenized sample. Then, the mixture was pressed as cylinder parts with height and diameter of 1 cm, with compaction pressures of 300, 500, and 700 MPa and sintered at 1000 °C for an hour under pure argon atmosphere.

### 4. Results and Discussion

To study the formation of phases in the samples, synthesized by precipitation method, the X-ray diffraction technique was used. Figure 1 shows the XRD diffraction pattern of the calcium hydroxide. According to this Figure, it can be seen that the reaction (5) has been completely performed and there is not any unreacted materials in this condition of precipitation. It proves that the duration times for the experiments were suitable.

![Figure 1. The XRD diffraction pattern of calcium hydroxide](image)

In order to study the formation of hydroxyapatite and its evolution during heating time, the samples were calcined at 700 °C without Ti powder. Fig. 3 shows the XRD pattern of the calcined Ca(OH)\textsubscript{2} and DAP sample. As it shows, two types of calcium phosphates were synthesized and later they will transform to hydroxyapatite in 1000 °C by reaction (6):

![Figure 2. SEM image of synthesized calcium hydroxide](image)
In Situ Formation of Hydroxyapatite During Powder Metallurgy Preparation of Porous Ti/HA Nano Composite: A Candidate for Dental Implants

The temperature of 700 °C was selected because it was the nearest temperature to HA formation. These hydroxyl groups can cause synthesis of hydroxyapatite and partial oxidation of titanium. Therefore, according to the primary objective of this project, hydroxyapatite was synthesized next to the titanium and the composite of Ti/HA was formed. On the other hand, the presentation of titanium oxide and calcium titanate in dental implants will not be harmful and will not affect its function due to the fact that these compounds are inert and they will not react with titanium and hydroxyapatite.

Also, Fig. 5 shows that the pattern of the sample, pressed with the pressure of 700 MPa, is sharper than the other samples. In other words, the sharpness of the main peak corresponds to perfect crystallization of HA in this sample. The reason is that at higher pressure, the reactants of \( \text{Ca}_2\text{P}_2\text{O}_7 \) and \( \text{CaPO}_3\text{OH} \cdot 2\text{H}_2\text{O} \) are closer to each other and hence affects the reaction kinetics and diffusion process.

Table 1 shows that while the compaction pressure has increased, the apparent and bulk densities have also increased. In addition, it shows that open porosities in samples have decreased with increasing the compaction pressure. According to the purpose of this research, which is preparation of dental implant with adequate open porosities, the morphology and porosity distributions are the most important parameters, so the assessment of compaction pressure should be studied.

For detailed evaluation of open porosity, morphology of particles, and elemental analysis, after pressing and sintering, the samples were examined using scanning electron microscope. Figures 6 to 8 show the images taken by this microscope.
As these figures show, with the increasing compaction pressure of 300 to 700 MPa the amount of open porosity extremely reduced because the particles have become closer and the spaces between them have reduced. On the other hand, with increasing the compaction pressure, the grains with regular geometric shape have increased and their distribution throughout the sample is quite evident. These grains which have hexagonal-like sections are marked in Figures 7 and 8. We have these particles as a result of the reaction between \( \text{Ca}_2\text{P}_2\text{O}_7 \) and \( \text{CaPO}_3\text{(OH)}\cdot2\text{H}_2\text{O} \) which led to hydroxyapatite. The images indirectly confirmed the results of XRD that the grains in pressed samples at a compaction pressure of 700 MPa, have shown more perfect crystallization.

## 5. Conclusions

1. According to the results of XRD, it was found that after calcination of mixed \( \text{Ca(OH)}_2 \) and DAP at 700 °C, \( \text{Ca}_2\text{P}_2\text{O}_7 \) and \( \text{CaPO}_3\text{(OH)}\cdot2\text{H}_2\text{O} \) were obtained. SEM results showed that the particle size is in the range of 1 to 5 microns and morphology of these particles are imperfect hexagonal.

2. Sintering of mixed titanium and calcined powders at 1000 °C, led to the formation of composites of titanium, hydroxyapatite, titanium oxide, and calcium titanate.

3. Compaction pressure of 700 MPa caused perfect crystallization during sintering. Therefore, it was much better than the other compaction pressures. Also, in 700 MPa, bulk density and the percentage of open porosities were 3.07 g/cm³ and 28.2%, respectively. Moreover, with increasing the compaction pressure, open porosities decreased and the number of grains with regular geometric shapes increased.
