Abstract – The effect of soil contamination by polycyclic aromatic hydrocarbons (PAH) and heavy metals on earthworms and enchytraeids was studied in urban parks, in Brno, Czech Republic. In spring and autumn 2007, annelids were collected and soil samples taken in lawns along transects, at three different distances (1, 5 and 30 m) from streets with heavy traffic. In both seasons, two parks with two transects each were sampled. Earthworms were collected using the electrical octet method. Enchytraeids were extracted by the wet funnel method from soil cores. All collected annelids were counted and identified. Basic chemical parameters and concentrations of 16 PAH, Cd, Cu, Pb, and Zn were analysed from soil from each sampling point. PAH concentrations were rather low, decreasing with the distance from the street in spring but not in autumn. Heavy metal concentrations did not decrease significantly with increasing distance. Annellid densities did not significantly differ between distances, although there was a trend of increase in the number of earthworms with increasing distance. There were no significant correlations between soil content of PAH or heavy metals and earthworm or enchytraeid densities. Earthworm density and biomass were negatively correlated with soil pH; and enchytraeid density was positively correlated with soil phosphorus.

Index Terms: Enchytraeidae, Lumbricidae, soil pollution.

Introduction

The major groups of pollutants emitted by motor vehicles are heavy metals (HM) and polycyclic aromatic hydrocarbons (PAH). The soil fauna of urban greens is particularly exposed to these pollutants. A number of studies have shown that species richness and diversity of earthworms decreased along a gradient of metal pollution (Pižl & Josens, 1995; Nahmani & Lavelle, 2002; Lukkari et al., 2004), and most laboratory ecotoxicity tests or field studies have shown negative effects of metals on survival, growth, feeding activity and reproduction of earthworms (Cikutovic et al. 1993; Khalil et al. 1996; Kula & Larink, 1998). Several studies have also dealt with heavy metal (HM) effects on enchytraeids in the field, usually in

The effects of polycyclic aromatic hydrocarbons

regard of pollution by metallurgical plants. However, the reported results are not consistent. Bengtsson & Rundgren (1982) observed a clear detrimental effect of copper, zinc and lead contamination on enchytraeid species diversity, densities and occupation of the organic soil layer; however, Kapusta et al. (2003) did hardly find any direct effect of elevated concentrations of these three elements and cadmium.

Much less is known about the effects of PAH on soil invertebrates. The ability of soil organisms, such as earthworms, to survive in the presence of both carcinogenic and narcotic PAH is reflected by their capacity to transform and excrete such chemicals (Milligan et al., 1986). Several authors reported the negative effect of PAH on the survival and reproduction of earthworms (Son et al., 2003; Brown et al., 2004; Contreras-Ramos et al., 2006; Eom et al., 2007) and enchytraeids (Sverdrup et al., 2002a, 2002b), as measured in different types of toxicity tests. Nevertheless, Eijsackers et al. (2001) concluded that PAH-contaminated sediments have no significant ecotoxicological impact on earthworms; and Ersfeld & Snow-Ashbrook (1999) revealed even positive associations of the growth of the earthworm Eisenia andrei with PAH concentrations, in toxicity testing of contaminated industrial soils.

Didden & Römbke (2001) gave an overview of our present knowledge on the impact of soil contaminants on enchytraeids, pointing out the overall suitability of enchytraeids for monitoring purposes, but also the data deficiency in regard of PAH, the need of combining laboratory and field studies, and the interspecific differences in enchytraeid reactions to pollutants. Achazi et al. (1999) showed Enchytraeus crypticus to be hardly affected by PAH, as to survival and reproduction, but to avoid substrate contaminated by some PAH (fluoranthene) while tolerating others (benzo[a]pyrene). The study of Kobetičová et al. (2007) is probably so far the only one looking at the effect of PAH and HM contamination on enchytraeids in soils exposed to emissions of motor vehicles. In this study, soils were sampled in the field, but their effect was tested in the laboratory using cultures of Enchytraeus crypticus. While PAH concentrations were clearly elevated due to heavy traffic, no clear relationship for heavy metals was found. Toxicity tests did not show any detrimental effect on enchytraeid survival and reproduction.

The objective of our study was to assess the concentrations of PAH and HM in soil of urban parks, and their relationships to soil-dwelling annelid assemblages (earthworms and enchytraeids) in these parks.

Materials and Methods

The impact of soil pollution on terrestrial annelids was investigated in two public parks in the city of Brno (Czech Republic). Two lawns, both adjacent to a street with high traffic intensity, were selected as sampling sites. Samples were taken in 1, 5 and 30 m distance from the street, in spring and autumn 2007 (two transects per lawn and sampling date). Each sampling point included four adjacent soil cores (each of 17 cm² working area, 12 cm depth) for enchytraeid extraction, and one sampling point (working area of 1250 cm²; Worm-Ex III device) for earthworm extraction by the electrical octet method (Thielemann, 1986). Enchytraeids were extracted from the cores for 48 hours by the wet funnel method without heating (Römbke et al., 2006). The obtained specimens were counted and identified alive. For enchytraeids, the data for the four soil cores, taken at a given sampling point and date, were pooled. The number of replicates used for further analysis was the same for both annelid taxa (four sampling points per distance and date, half of those in one park and half in the other).

Two sets of soil samples were taken from each sampling point using Kopecky soil sample rings to analyse basic chemical parameters and PAH and HM contents. The contents of sixteen polycyclic aromatic hydrocarbons (N, ACY, ACE, FLU, PHE, AN, F, PY, B(a)A, CH, B(b)F, B(k)F, B(a)P, I(123cd) P, D(a, h)A, B(ghi)PE) and four heavy metals (Cd, Cu, Pb, Zn) were determined using atomic absorption spectrophotometry.

Worm density and biomass (the latter for earthworms only) and soil concentrations of PAH and HM, at different distances from the street, were compared using ANOVA. The effects of selected environmental parameters on soil annelids were evaluated using multidimensional statistics (Canoco programme).

Results and Discussion

Four species of earthworms were recorded, the anecic Lumbricus terrestris and the endogeic Aporrectodea caliginosa being highly predominant.
The proportions of both species were similar at all distances from the street (Figure 1). However, the proportion of *Allolobophora chlorotica* increased, and that of *Aporrectodea rosea* decreased slightly, with increasing distance from the street.

In spring, earthworm densities were extremely low, ranging from 0 to 32 individuals m\(^{-2}\). This was probably caused by an unusually dry and warm early spring. In autumn, earthworm density tended to increase from the street edge towards the centre of the park, with mean values of 116, 186 and 216 individuals m\(^{-2}\), at 1, 5 and 30 m distance from the street, respectively (Figure 2). However, the differences were insignificant (p = 0.48).

The enchytraeid community was dominated by *Henlea ventriculosa*, *Buchholzia appendiculata*, *Enchytraeus buchholzi* s.l., three *Achaeta* species and *Fridericia* spp., particularly *F. hegemon* (Figure 1). The r-strategist *B. appendiculata* was present only close to the streets, whereas there was no clear trend

![Figure 1. Proportions of individual species of earthworms and enchytraeids, in urban lawns with increasing distance from the street.](image1)

![Figure 2. Densities (mean±SE) of earthworms and enchytraeids, in urban lawns with increasing distance from the street.](image2)
in the distribution of the other r-strategist present, *E. buchholzi* s.l. (including co-geners not identified to species). Of the other enchytraeid species present, only *Achaeta* species (tolerant to soil compaction) showed some trend, reaching a higher representation in 5 m distance from the streets.

Enchytraeid densities in spring were very low, with mean values of 4,779, 993 and 1,507 individuals m\(^{-2}\) at the distances 1, 5 and 30 m, respectively (Figure 2). The corresponding values for the autumn samplings were 5,331, 8,309 and 4,890 individuals m\(^{-2}\). The differences were not significant, and there was by no means a trend of densities increasing with the distance to the streets.

The content of PAH in soil was relatively low and ranged from 3.2 to 17.65 mg kg\(^{-1}\) in spring, and from 2.9 to 8.1 mg kg\(^{-1}\) in autumn (Figure 3). It decreased with the distance from the street (p = 0.05) in spring, but not in autumn. No significant effect of the distance from the street on the contents of HM in soil was recorded. Surprisingly, there was a trend of increasing HM concentrations, in particular that of Zn, from the street edge towards the centre of the lawn (Figure 4).

There were no significant correlations between soil content of PAH and the density of earthworms and enchytraeids (Figure 5). This could be explained by the presence of other environmental factors, which could mitigate the often shown toxicity of PAH for earthworms (Brown et al., 2004; Contreras-Ramos et al., 2006). Erstfeld & Snow-Ashbrook (1999), who found positive associations of soil invertebrate communities with PAH concentrations, in soils of

industrial sites in Tennessee, USA, suggested that this might be a response to increased populations of soil microflora capable of metabolizing PAH. In addition, enchytraeids seem to be much less sensitive to PAH toxicity than earthworms, as shown by Sverdrup et al. (2002a, 2002b). Also Kobetičová et al. (2007) found no toxic effect of PAH contamination on the tested enchytraeid species. Enchytraeids might avoid soil of higher PAH contamination levels, but this might also depend on the actual compounds present (Achazi et al., 2002a, 2002b). Also Kobetičová et al. (2007) found no toxic effect of PAH contamination on the tested enchytraeid species. Enchytraeids might avoid soil of higher PAH contamination levels, but this might also depend on the actual compounds present (Achazi et al., 2002a, 2002b).

Earthworm density and biomass were negatively correlated with soil pH (p<0.05). The density of enchytraeids was positively correlated with total (p<0.01) and available (p<0.05) soil phosphorus. The content of HM in soil did not correlate significantly with the densities of earthworms and enchytraeids. This corresponds with the results by Hobbelen et al. (2006), who did not find direct effects of metal pollution on earthworms, isopods and millipedes, in a contaminated floodplain area in the Netherlands, though metal concentrations in soils were very high. Also Kapusta et al. (2003) did not find any direct effects of heavy metals on enchytraeids. Possible explanations for these results are an adaptation of detritivores to metal pollution, or the presence of other more important factors overruling toxicity effects.

Conclusions

1. Soil concentrations of polycyclic aromatic hydrocarbons and heavy metals in Brno parks do not decrease with increasing distance from the street.
2. Neither earthworm density or biomass nor enchytraeid density in Brno park lawns increase with increasing distance from the street.
3. Neither earthworm density or biomass nor enchytraeid density in Brno park lawns seem to be affected by elevated concentrations of polycyclic aromatic hydrocarbons or heavy metals in soil.
