The aim of this study was to evaluate and to compare the possible inflammatory changes by screening acute phase proteins concentrations in healthy bitches subjected to ovariohysterectomy. Minimally invasive and conventional (laparotomy) ovariohysterectomies were performed in 17 client-owned adult female mixed breed dogs. Nine animals were subjected to minimally invasive and eight animals to conventional ovariohysterectomy. Blood samples were taken before surgery, 24, 48 hours, and seven days postoperatively. Serum C-reactive concentration was determined by a commercial ELISA kit and serum haptoglobin concentration was measured via hemoglobin binding assay, both previously validated for use in dogs. As the data did not meet the normal distribution criteria, the nonparametric Kruskall-Wallis was performed to compare quantitative variables between groups. One-way ANOVA and the Friedman test were used for multiple comparisons between time points, with a P<0.05 considered significant. C-reactive protein concentration was significantly different (P<0.0001) at 24 hours postoperatively between groups. There was no significant difference in haptoglobin concentration between groups. C-reactive protein and haptoglobin concentrations were significantly different at 24 and 48 hours postoperatively for minimally invasive and conventional ovariohysterectomies. These findings provided an overview of the short-term inflammatory effects produced by minimally invasive and conventional ovariohysterectomies.

INDEX TERMS: Bitches, ovariohysterectomy, dogs, C-reactive protein, haptoglobin, surgery.
The acute phase response is part of the body’s innate defense system (Eckersall & Bell 2010), characterized by a systemic reaction caused by local or systemic disorders, promoted by infectious agents, trauma, and tissue injury, surgeries, neoplastic growth or immunological disorders (Ceron et al. 2005, Gruys et al. 2005, Eckersall 2008). During the acute phase response, there is increased synthesis and release of acute phase proteins (APP), induced by pro-inflammatory cytokines produced mainly by the liver and extrahepatic tissues such as adipose tissue, mammary gland and lungs. PFAs are classified according to changes in their concentrations in positive (C-reactive protein, haptoglobin, serum amyloid A) if they increase, or negative (albumin), if they decrease their concentrations during the acute phase response (Murata et al. 2004, Ceron et al. 2005).

Ovariohysterectomy is one of the most performed surgical procedures in companion animals and promotes the appearance of pain signals during the postoperative period in dogs (Lascelles et al. 1998). To minimize surgical trauma, minimally invasive techniques, such as endoscopic or laparoscopic surgeries, have been used as they cause less inflammatory reaction when compared to conventional surgical techniques (Suter et al. 2002, Kjelgaard-Hansen et al. 2013). In addition, the response to surgical stress is composed of a set of hormonal, metabolic and inflammatory reactions that occur after surgery, allowing the body to adapt to trauma and to recover damaged tissues (Jacobsen et al. 2009). In order to improve the surgical procedure and monitoring of the postoperative period, it is necessary to identify markers that are useful to evaluate the intensity of the trauma caused by the procedure. Recent investigations have demonstrated changes in APP concentrations in dogs related to the extent and progression of diseases, as well as their the inflammatory response in infectious, parasitic, trauma, degenerative diseases and neoplastic diseases (Bayramli & Ulutas 2008, Koster et al. 2009, Tecles et al. 2009, Méndez et al. 2014, Schmidt & Eckersall 2015, Hillström et al. 2016, Schmidt et al. 2016). However, although the acute phase response was investigated in dogs undergoing elective soft tissue surgeries (Serin & Ulutas 2010, Kjelgaard-Hansen et al. 2013, Kum et al. 2013), surgical correction of obstructive airway syndrome (Planellas et al. 2015), nephrectomy (Schmidt et al. 2016), and ovariohysterectomy as the treatment of pyometra (Dabrowski et al. 2007, 2009) few studies have evaluated the PFA concentrations and the acute phase response dynamics in dogs undergoing minimally invasive surgical procedures (Mathon et al. 2011, Tvarijonaviciute et al. 2011, Kjelgaard-Hansen et al. 2013).

Therefore, the objective of this work is to evaluate and to explore possible differences between two conventional and minimally invasive ovariohysterectomy protocols in bitches regarding the kinetics of the acute protein response of CRP (C-reactive protein) and Hp (haptoglobin), comparing the effects of inflammation caused by the two procedures in the postoperative period.

MATERIALS AND METHODS
The study population comprised of 17 client-owned adult female mixed breed dogs (2 to 7 years old; 10±1.2kg), admitted to the São Paulo State University Veterinary Teaching Hospital of the Faculty of Veterinary Medicine and Animal Science (FVMZ) for elective ovariohysterectomy. Inclusion criteria included the availability of complete clinical records as part of the routine care and ultrasound evaluation discarding pregnancy. The stage of oestrus cycle was not determined. The dogs included in the study showed no abnormal findings on physical and clinical examination or any other considerable change in hemograms, alanine aminotransferase activity, total serum protein, albumin, and fibrinogen. This approach was approved by the Faculty’s Animal Experimentation Ethics Committee of the São Paulo State University, FVMZ-Unesp, Campus Botucatu (protocol number 194/2011-CEUA) with the consent form signed by the owners under the same protocol.

The animals were fasted (food and water) for 12 hours before the surgical procedure. All bitches received meloxicam (0.2mg/kg, Maxicam 0.2%, Ourofino, Brazil) pre-surgery. 15 minutes before induction of anesthesia. At the same time, the preanesthetic medication used was the combination of acepromazine maleate (0.05mg/kg; Acepran 0.2%, Vetnil, Brazil) and morphine (0.5mg/kg; Dimorf, Cristalia, Brazil) via intramuscular. For anesthesia induction, the combination of ketamine (10mg/kg; Quetamina, Vetnil, Brazil) and diazepam (0.5mg/kg; Valium, Roche, Brazil) were used intravenously. The anesthetic protocol employed was adequate for performing the surgical procedure and lasted from 20 to 30 minutes, with no need for anesthetic complementation. After the surgical procedure, the animals received intravenous penicillin benzathine (24,000 IU, Veterinary Pentabiotic, Fort Dodge, Brazil) as a routine prophylactic measure.

The dogs were divided into two experimental groups. Group 1 (G1): 9 animals, submitted to ovariohysterectomy by the conventional technique. Group 2 (G2): 8 animals, submitted to ovariohysterectomy by the minimally invasive technique. The conventional technique was performed by laparotomy. After the procedures of trichotomy and asepsis of the abdominal region, a ventral midline incision was performed over the skin, subcutaneous tissue and the linea alba. Then the uterus was exposed and the ligatures of the ovarian pedicles and uterine body were performed with mononylon 2-0 yarn. Once the uterus and ovaries were removed, the abdominal wall synthesis was performed with Sultan-type suture, and subcutaneous tissue using a simple continuous pattern of absorbable sutures and the skin was closed in a simple interrupted pattern. The stitches were removed seven days after the surgical procedure (Stone 2007).

For the minimally invasive technique, the animals were placed in dorsal decubitus position. After the trichotomy and asepsis of...

the region of the abdomen, a midline skin incision of about two centimeters was performed caudal to the umbilical scar. Then the linea alba was incised and the abdominal cavity was accessed. The uterine horns and the ovarian pedicles were pulled into a midline portal with the aid of a spay hook and the ovarian ligament dissected, thus pulling the ovaries and ovarian pedicles which were ligated with a self-static nylon cable tie. Subsequently, the uterine horns were pulled into the midline incision and the cervix was ligated using the same nylon cable tie. Abdominal wall synthesis was performed with Sultan-type suture, and subcutaneous tissue using a simple continuous pattern of absorbable sutures and the skin was closed in a simple interrupted pattern as described by Silva et al. (2004) and Lima et al. (2010). All surgical procedures of G1 and G2 were performed by a single surgeon, but a different person for each group.

Blood samples were obtained by jugular vein puncture 24h preoperatively (M1) and at three time points postsurgery, i.e. 24h (M2), 48h (M3), and on day 7 after surgery (M4). Aliquots of the samples (3mL) were placed in plain tubes with gel separators (BD Vacutainer® Blood Collection Tube; Becton, Dickinson and Company, USA) were allowed to clot at room temperature, centrifuged (1,500x g for 5 min) and the harvest sera were stored in Eppendorf microtubes (Eppendorf, Hamburg, Germany), stored at -20°C with CRP and haptoglobin analyses performed within six months.

Serum CRP concentrations were determined by a commercial ELISA kit (cCRP; Avacta, York, UK) based on a previous assay validated for use in dogs (Eckersall et al. 1989). Serum HP concentrations were measured via a hemoglobin binding assay previously validated for use in dogs (Crawford et al. 2013). These assays showed a within run imprecision of less than 10%.

All statistics were performed using statistical software (GraphPad Version 6 for Windows, GraphPad Software Inc., San Diego/CA, USA). All variables were first assessed for normality using the Shapiro-Wilk test. The nonparametric Kruskal-Wallis test was used to compare the groups and One-way ANOVA and Friedman test was used for multiple comparisons between groups as the data was not normally distributed. Mann-Whitney U test was used for additional comparisons between groups. Statistical significance was set at P<0.05 for all analyses.

RESULTS

The preanesthetic and anesthetic protocols were adequate to perform the surgical procedures in both groups. Surgical procedures ranged from 20-30 minutes in G1 and 15-20 minutes in G2. There were no intercurrences or complication in all performed surgeries, regardless of the technique employed, until the stitches were removed.

Haptoglobin and CRP concentrations from all dogs of G1 and G2 are presented in Table 1. C-reactive protein concentration was significantly higher (P<0.0001) at 24h after the surgical procedures for both ovariohysterectomy techniques. There were no significant differences for Hp between both surgical protocols. The median concentrations of CRP were significantly higher when comparing 24 and 48h after surgery to before minimally invasive and conventional ovariohysterectomy. In our study, the median haptoglobin concentrations were significantly higher 48h after conventional ovariohysterectomy and at 24 and 48h after the minimally invasive surgery.

Significant differences for G1 and G2 were not observed for CRP and Hp on day 7 after surgeries (Table 1).

G1 = Conventional ovariohysterectomy. G2 = minimally invasive ovariohysterectomy. Different capital letters in the same line indicate significant difference between surgical protocols, lowercase letters in the same column indicate significant difference between time points.

DISCUSSION

CRP is the major acute phase protein in dogs and also a consistent marker of inflammation in this species, stimulated by the inflammatory response increasing up to 10- to 100-fold (Ceron et al. 2005, Eckersall 2008). Haptoglobin is considered a moderate acute phase protein in dogs and has also been used as a nonspecific biomarker of inflammation, but there is an APP pattern that has been described in dogs with hyperadrenocorticism (McGrotty et al. 2003, Caldin et al. 2009) and in dogs infected by the giant kidney worm (Dioctophyme renale) (Schmidt et al. 2016), with increased Hp concentration indicating a stress response due to increased endogenous cortisol concentration (Caldin et al. 2009).

The acute phase response observed in the dogs of this study consisted of increased CRP and Hp serum concentrations after ovariohysterectomy. These increases are related to the inflammatory response induced by pro-inflammatory cytokines interleukin-1, interleukin-6 and alpha tumor necrosis factor, which stimulate synthesis and release of APP by the liver (Gruys et al. 2005, Eckersall 2008). In our study, these results could evidence an acute inflammatory response as the median concentrations of CRP and Hp were above the reference intervals for dogs (CRP <12µg/mL, Hp<3 g/L) (Eckersall et al. 1999, Ceron et al. 2005), from 24 hours after the surgical procedure, similarly to those described previously for acute phase proteins after surgical trauma in dogs (Conner et al. 1988, Dabrowski et al. 2007, 2009, Tvarijonaviciute et al. 2011, Kjelgaard-Hansen et al. 2013, Schmidt et al. 2016).

The increased CRP concentrations at M2 found in dogs after conventional and minimally invasive ovariohysterectomy could reflect the systemic reaction of the surgical trauma. Bitches subjected to ovariohysterectomy by laparotomy demonstrated a cumulative increased CRP concentration post surgery, peaking at 12h after the surgical procedure indicating that this could be the appropriate time point to evaluate the inflammatory impact of surgical trauma (Kjelgaard-Hansen et al. 2013). This response was also expected in our study; however, despite
increased CRP at 24h postsurgery, this result indicates a limitation of our investigation as it was not possible to obtain serum samples at the immediate postsurgical time points, i.e. at 4, 8, and 12h, as described by Kjelgaard-Hansen et al. (2013).

Conner et al. (1988), Dabrowski et al. (2009), and Kum et al. (2013) demonstrated that CRP concentration reaches a peak at 24h after the surgical trauma and there is a rapid decrease of CRP in the absence of postoperative complications. However, there was a different inflammatory response in bitches subjected to ovariohysterectomy by laparotomy with increased CRP concentrations from 24h until day 7 after surgery, demonstrating that although there could have been a decrease in inflammation, CRP remained increased (Serin & Ulutas 2010). No changes were observed in CRP concentration on day 7 postsurgery of the female dogs evaluated in this study. Despite the ovariohysterectomy technique, this indicates that the recovery from the inflammation associated with the surgery was complete.

In our study, no changes were observed for Hp concentrations between both surgical protocols. However, a hypothesis explaining why dogs subjected to conventional ovariohysterectomy present decreased serum Hp concentration at 24 and 48h post-surgery compared to dogs subjected to minimally invasive ovariohysterectomy would be that the highest degree of hemolysis immediately after surgery (24h) occurs due to a larger tissue injury and the decrease in Hp concentration could be caused by the monocyte/macrophage Hp-hemoglobin receptor expressed on Kupffer cells in the liver and the further removal of this complex (Conner et al. 1988, Eckersall 2008).

Haptoglobin is a moderate APP and usually peaks at 24 to 48h after a surgical trauma (McGrotty et al. 2003, Eckersall 2008). Haptoglobin concentrations were above reference intervals for the bitches (Hp<3g/L) (Eckersall et al. 1999) at 24h after the minimally invasive ovariohysterectomy as well as at 48h for both surgical procedures. These results could indicate a mild inflammatory response that could be associated with an inflammatory response of lower intensity after the initial surgical trauma. Dabrowski et al. (2009) and Serin & Ulutas (2010) demonstrated the same inflammatory response in bitches subjected to ovariohysterectomy by laparotomy.

Repeated measurements of CRP and Hp were useful in monitoring the short-term inflammatory process induced by the ovariohysterectomy that was associated with increases in serum concentration of both APPs. No further significant increases were recorded 7 days after conventional and minimally invasive ovariohysterectomy, when recovery from the inflammation associated with the surgery was complete.

CONCLUSIONS

Bitches were subjected to conventional and minimally invasive ovariohysterectomy that contributes towards an understanding of the postsurgical inflammatory response in dogs subjected to elective ovariohysterectomy. Both surgical procedures increased CRP and Hp concentrations at different time points due to surgical trauma, demonstrating the usefulness of determining the concentrations of these proteins to monitoring the short-term inflammatory process induced by the ovariohysterectomy.
