Summary

Arteriovenous malformations (AVMs) of the scalp are rare lesions. The clinical picture presents with complaints of increased scalp, scalp disfigurement, pain and neurological symptoms. Its origin can be congenital or traumatic. We present a case of giant scalp AVMs and its management, followed by a brief literature review on the subject. The diagnosis of scalp AVMs is based on physical examination and confirmed by internal and external carotid angiography or computed tomographic angiography (CTA). Surgical excision is especially effective in scalp AVMs, and is the most frequently used treatment modality.

Keywords: scalp, arteriovenous malformations, vascular diseases.

Introduction

Extracranial scalp arteriovenous malformations (AVMs) are relatively rare, accounting for only 8.1% of cases of AVMs.1 They are vascular aberrations that develop during the fetal period and result from failure of embryonic vasculature to differentiate into arteries and veins.2 Although controversy exists regarding the cause of these lesions, it is generally accepted that they may be either congenital or traumatic in origin.3 The clinical picture is characterized by increased scalp, scalp deformation, pulsatile mass, headache, tinnitus, convulsion, bleeding and dizziness, but it can often be asymptomatic. Diagnosis of AVMs is based on physical examination and confirmed by internal and external carotid angiography, or computed tomographic angiography (CTA).4 Treatment options include endovascular occlusion, direct percutaneous injection of sclerosing agents and, in selected cases, surgical resection.5

We present a case of scalp AVM and its management at our institution. We provide below a brief literature review and some commentaries regarding the clinical and radiological features of this rare entity.

Case report

We present the case of a 33-year-old male with a complaint of a pulsatile and increasingly bigger mass within the left temporo-occipital region of scalp for 3 years. There was no previous trauma. We identified an area of focal thickening of the scalp, above the lateral and occipital skull surfaces, soft and pulsatile on palpation. There was no audible bruit or any abnormalities on neurologic examination. The CTA demonstrated a lesion of vascular nature, presumably an arteriovenous malformation beneath the scalp. There was a nidus fed by branches from ipsilateral superficial temporal and occipital arteries (Figure 1). There was no communication with the intracranial circulation. The treatment of choice was surgical, with ligation of the feeder branches without scarifying parent vessels, with total excision of the malformation. Scalp irrigation was preserved (Figure 2). Postoperative period was uneventful, and postoperative CTA showed no significant and/or pathologic vessels left (Figure 3).

![Figure 1](http://dx.doi.org/10.1590/1806-9282.62.09.828)
AVMs of the scalp are abnormal fistulous connection between the feeding arteries and draining veins, without an intervening capillary bed within the subcutaneous layer. Their rarity and unpredictable behavior render systematic studies, assessment of prognosis, and treatment controversies.

Different names have been used to describe these lesions, and the most common are cirrhotic aneurysm, plexiform angioma, scalp arteriovenous fistula, arteriovenous aneurysm and arteriovenous malformation.

Almost all patients present with a scalp swelling that has gradually increased in size from birth or after head trauma. Rapid increases in size have been reported to occur at puberty, during menstruation and during pregnancy. Their clinical signs are associated with the size of AVMs. Associated symptoms and signs include pain, throbbing headaches and bruising, hemorrhage, seizures and psychomotor retardation.

Large lesions have also been associated with scalp necrosis.

AVMs cause direct shunting of high-volume arterial blood through low-resistance arteriovenous fistulae, often resulting in venous hypertension, hypoperfusion of vessels and tissue downstream, and reduced cerebral perfusion, known as the steal phenomenon.

About 10 to 20% of scalp AVMs develop following penetrating or non-penetrating trauma to the scalp.

Total excision of a scalp AVM requires comprehensive knowledge of the feeding arteries, draining veins and nidus. Catheter angiography has been the gold standard for diagnosis, but CTA can also provide a very high imaging resolution and the observation of related bony structures, which may be important for surgical planning, as in the case of our patient.

Treatment of scalp AVMs allows many possibilities and individualization is key. Surgical excision is especially effective in selective cases, when endovascular treatment is difficult or not feasible. Moreover, successful endovascular treatment of scalp AVMs has been reported, but has often been found to be insufficient for those with more extensive fistulae or with other complicating components.

In relation to surgical treatment, common complications consist of hemorrhage, necrosis of the scalp, and sepsis caused by wound infection. Hemorrhage may be prevented with preoperative embolization, clamping, and suturing of feeding vessels. Several authors recommend preoperative endovascular treatment to reduce blood supply of large lesions, to facilitate surgery.

**Resumo**

Malformação arteriovenosa gigante de escalpo

Malformações arteriovenosas (MAV) do couro cabeludo são lesões raras. O quadro clínico apresenta-se com queixas de aumento do couro cabeludo, desfiguração do couro cabeludo, dor e sintomas neurológicos. A origem pode ser congênita ou traumática. Apresentamos um caso de MAV gigante de couro cabeludo e o tratamento adotado, seguindo-se uma breve revisão da literatura. O diagnóstico das MAV de couro cabeludo baseia-se no exame físico e é confirmado pela angiografia carótida interna e externa ou angiografia por tomografia computadorizada. A excisão cirúrgica é especialmente eficaz em MAV de couro cabeludo e é a modalidade de tratamento mais frequentemente utilizada.
