INTRODUCTION

In the current review, we will be addressing the challenges of mesenchymal stem cell therapy (MSCs), as these cells are already being tested in human clinical studies.

MESENCHYMAL STEM CELLS (MSCs)

MSCs, also known as stromal stem cells, are a diverse cell population with a wide range of potential therapeutic applications for different organs and tissues. MSCs can be derived from many tissue
MESENCHYMAL STEM CELL THERAPY IN ACUTE KIDNEY INJURY (AKI): REVIEW AND PERSPECTIVES

sources consistent with their possibly ubiquitous distribution.

These cells are characterized by clonogenicity, self-renewal, differentiation in different lineages and by regenerating organs with certain lesions. The International Society for Cellular Therapy has proposed a series of criteria for defining human MSCs (H-MSCs), namely: (1) adherence to plastic under standard culture conditions; (2) expression of CD73, CD90, CD105 surface molecules in the absence of CD34, CD45, HLA-DR, CD14 or CD11b, CD79α or CD19; (3) differentiation capacity for osteoblasts, adipocytes and chondroblasts in vitro (1). These criteria have been established to standardize the isolation of MSCs from humans, but may not apply uniformly to other mammals.

CELL THERAPIES USING MSCS IN SMALL ANIMALS

In Figure 1, we describe the main effects of MSCs extracted from different sites in the preclinical acute rodent models, including IR AKI by renal pedicle clamping, chemotherapy AKI (cisplatin), and kidney transplantation itself2-9.

Despite the evidence that cell therapy with MSCs contributes to the improvement of AKI, some challenges need to be overcome in order for such therapy to be successfully established, such as defining the best route of administration, the number of cells per administration and also the number of injections, the best strategy for MSCs to migrate to acute and chronic kidney injury, understanding the interaction between MSCs and other tissue cells, and to identify adverse effects of MSCs (poorly differentiated in vivo and tumour formation).

Meta-analysis studies evaluating the therapeutic effect of MSCs in small animals in chronic and acute models of renal injury with variable administration (arterial, venous or renal) have shown beneficial effect for renal regeneration10. However, it is suggested that the arterial route enables renal regeneration more efficiently than the intravenous route. Intrave-

FIGURE 1. MAIN EFFECTS OF MESENCHYMAL STEM CELLS EXTRACTED FROM BONE MARROW, ADIPOSE TISSUE AND UMBILICAL CORD IN SEVERAL MODELS OF AKI BY RENAL PEDICLE CLAMPING ISCHEMIA-REPERFUSION, CHEMOTHERAPY (CISPLATIN) AND KIDNEY TRANSPLANTATION.
nously, cell number, multiple injections, and cell size increase the chance of pulmonary entrapment. Although local intraparenchymal administration also has a beneficial effect on renal repair, this route is less practical for clinical application, especially since renal disease is diffuse.

Another emerging approach to MSC administration-based therapies includes understanding the role of exosomes in tissue regeneration. Exosomes (30-40 to 100-120 nm) are vesicles naturally secreted by membranes and present ubiquitous distribution. These extracellular vesicles are considered important mediators of cell-to-cell communication, also mediating the effects of MSCs on target cells, such as the transfer of receptors, proteins, and genetic information (mRNA and microRNAs), as well as having direct stimulation in target-cell.

A key aspect that may adversely affect the therapeutic potential of MSCs is the inflammatory environment at the site of injury, as it may directly impact survival and incorporation of these cells into the injured tissue. Thus, M2 macrophage-derived anti-inflammatory cytokines (IL-10, TGF-β1, TGF-β3 and VEGF) favour the growth of MSCs, while M1 macrophage-derived proinflammatory cytokines (IL-1β, IL-6, TNF-α and IFN-γ) inhibit the growth of MSCs in vitro. This observation indicates that the timing of MSC injection is crucial to the success of tissue repair.

However, further studies on renal models are still needed to evaluate this paradigm of transition from immune privilege to immunogenic state in MSC.

**CELL THERAPIES USING MSC IN HUMANS**

The number of registered clinical trials worldwide and applications for Investigational New Drugs (IND) submitted to the US Food and Drug Administration (FDA) have recently increased, as well as the diversity in donor and tissue sources and therapeutic purposes, despite the considerable heterogeneity in the protocols. Most MSC trials included allogeneic cells occurring in the US, Europe, and China: phase 1 only (26%), phase 1/2 (40.6%), phase 2 only (22.5%), phase 2/3 (3.8%), phase 3 (6.7%) and phase 4 (0.3%). In 2019, 887 studies with H-MSCs were reported, 5% of which in renal diseases only, including AKI, DKD (diabetic kidney disease), kidney transplantation and nephritis, among others.

Another key aspect of MSC-based therapy is the isolation of MSCs from individuals with chronic diseases, such as DM, for autologous transplantation. Thus, AT-MSC obtained from diabetic donors present higher levels of cellular senescence and apoptosis than AT-MSC obtained from non-diabetic individuals, as well as the reduced capacity of osteogenic and chondrogenic differentiation. Similarly, type 2 diabetic patients treated with allogeneic UC-MSC (1x10⁶/kg), by intravenous injection followed by intrapancreatic endovascular injection, showed a reduction in glucose and glycated haemoglobin levels after a 12-month follow-up, as well as systemic inflammation markers (IL-1β and IL-6) and T lymphocyte count (CD3 and CD4). C-peptide levels also improved and insulin requirement decreased by ~30%. Thus, allogeneic versus autologous transplantation based on

</table>
the use of MSCs requires further investigation in the setting of DKD. On the other hand, in patients with ischemic cardiomyopathy, allogeneic and autologous BM-MSC were equally safe and effective.

In addition, some obstacles need to be overcome to achieve greater safety in MSC-based therapies such as cytogenetic aberrations observed during the propagation of these cells in culture. In humans, malignant transformation of MSCs has not been described in vivo so far in clinical trials. Another important aspect that should be taken into account in MSC cell therapy is the fact that its beneficial effect may be neglected by the occurrence of adipogenic differentiation during long-term follow-up, which may contribute to glomerulosclerosis.

In tables 1 and 2, we describe the main studies with MSCs in humans in the AKI scenario and after kidney transplantation, respectively. In Table 2, we describe both studies that evaluated safety and efficacy at the initial moment of transplantation and also at the later period. Currently, there are more than ten ongoing clinical studies involving a significant number of patients undergoing kidney transplantation, which means more than one thousand individuals. We highlight an ongoing clinical study with the inclusion of individuals undergoing renal transplantation and injection of two doses of autologous MSCs at weeks 6 and 7, and alemtuzumab induction followed by maintenance with everolimus and discontinuation of Tacrolimus from week 8 onwards.

An important point for the use of MSCs after kidney transplantation is the interaction between immunosuppressive drugs and the function of these cells. In vitro studies have shown that all immunosuppressant drugs (steroids, cyclosporine, sirolimus and mycophenolate) interfere in some way with the function of MSCs, leading to reduced production of...
trophic factors (HGF and VEGF) and TSG-6, which has immunomodulatory properties and antiapoptotic properties.

NEW PERSPECTIVES
Preconditioning or gene modifications of MSCs

Several approaches have been suggested to increase the efficiency of cell therapy with MSCs, such as preconditioning or gene modifications.

Preconditioning of MSCs

MSCs are generally grown in a 21% oxygen environment. However, physiologically, MSCs are found in an environment with a much lower oxygen tension (1% to 7%). Thus, the cultivation or preconditioning of MSCs in a hypoxic environment with 2% or 5% oxygen allows these cells to remain multipotent and have greater proliferative and migratory capacity, as well as lower senescence rates. In addition, hypoxia-preconditioned MSCs do not differentiate into tumour-associated fibroblasts in vitro and do not induce tumours in vivo.

In order to reduce the heterogeneity of the MSC profile, which is defined by the different isolation and culture protocols, the preconditioning of these cells with proinflammatory factors has been the focus of investigation. Thus, preconditioning of MSCs by stimulating IFN-γ, TNF-α, PGE₂ and nitric oxide mitigated the heterogeneous behaviour of MSCs in T lymphocyte proliferation trials and late type hypersensitivity response.

MSCs: gene carriers or gene modifications

Due to their migratory capacity to lesion sites, MSCs represent a robust platform for “delivery” of genes associated with regeneration and repair of renal tissue, working as a “Trojan Horse”. Thus, several genes associated with trophic factors have been studied for these purposes, IGF-1, HGF, EGF or VEGF, since they are renoprotective. Our group has been studying two genes, HGF and klotho, which have promising therapeutic potential in the future. We are modifying MSCs with these genes and will be injecting them into acute and chronic models of kidney injury.

In the context of IR or cisplatin-induced AKI, HGF is associated with increased tubular epithelial cell proliferation and migration, as well as lower α-SMA expression, fibrosis, and apoptosis. In chronic models such as murine DKD, HGF gene therapy increased the expression of SDF-1, which is the ligand of CXCR4 and, consequently, bone marrow cell migration to the kidney. Consequently, there was an improvement in proteinuria, a reduction in glomerulosclerosis (lower collagen I and IV deposition, and fibronectin) and TGF-β1 levels, a reduction in glucose and GLUT1-mediated glucose uptake, thus reducing oxidative stress. Similarly, in the murine Lewis mouse transplant model, HGF also reduced tubulointerstitial fibrosis, glomerulosclerosis and inflammation, leading to increased renal graft and animal survival.

Klotho is highly expressed in the distal tubule of the kidney. It is a co-receptor for fibroblast growth factor-23 (FGF-23) and participates in mineral homeostasis through interaction with other hormones such as parathyroid hormone (PTH) and 1,25-(OH)₂ vitamin D₃ in various tissues such as the kidneys, bones, intestines and parathyroid gland. There is a molecular signature of murine model klotho deficiency and CKD in humans, both related to serum creatinine values related to klotho expression in renal tissue, serum phosphorus and FGF23 values, atherosclerosis and ectopic calcification. In the kidneys, the soluble form of klotho has several effects and, therefore, therapeutic targets, such as antioxidant effects on cells (decreased senescence and apoptosis, as well as increased autophagy), inhibition of fibrosis, phosphorus reduction and FGF23, proangiogenic agents and maintenance of the stem cell reservoir, as well as reducing myocardial remodelling. Similarly, understanding the factors that decrease klotho expression in the kidney is equally important for establishing combined therapies to mitigate AKI damage and reduce CKD progression and, consequently, renal fibrosis. Factors that decrease kidney klotho expression include reduced kidney functional mass, abnormal cytokine production (↑ TNF-α and ↑ IFN-γ), increased oxidative stress (↑ lipid peroxidation and hydrogen peroxide), activation of the renin-angiotensin-aldosterone system (RAAS), reduction of vitamin D3, alteration of bone metabolism (hyperphosphatemia) and uremic toxins (↑ indoxyl sulphate).

In AKI patients, there is a proportional reduction in klotho expression according to the severity of the lesion. Thus, the administration of klotho protein, as well as the study of drugs that increase its production (statin and RAAS blockers, for example), reacti-
vation of endogenous expression of klotho by epigenetic mechanisms (demethylation and deacetylation) and/or cell therapy itself represent promising strategies. Thus, UC-MSC injection in rats subjected to IR injury restores kidney klotho expression, whereas genetically modified klotho-adenovirus MSCs lead to reduction of morphological and structural damage in the same model.

Other genetic modifications of MSCs, which are also quite promising in the context of AKI, include overexpression of erythropoietin, CXCR4, CTLA4Ig and IL-10/selectin, as well as transfection of biological drug-containing minicircles such as Etanercept, which is a TNF-α blocker and the transfection of nanoparticles containing iron oxide, polymers and plasmids.

Renal tissue-derived progenitors/stem cells

Several progenitors/stem cells specific to renal tissue have been studied in the literature, mainly in preclinical studies, and evaluated in acute and chronic models.

Recently our group demonstrated that c-Kit+ cells present in renal tissues have cardinal progenitor/stem cell properties, such as the ability to differentiate in different lineages of the mesodermal and ectodermal layers, clonogenicity, self-renewal and therapeutic potential in the AKI by IR model and acute puromycin-induced nephrotic syndrome in rats. In addition to paracrine effects, c-Kit cells have been incorporated around 10% in various renal compartments, such as tubular, vascular and glomerular, making them promising candidates for cell therapy. There is interest in defining whether MSCs can modulate c-Kit stem/progenitor cells in vivo or whether the combined infusion of these cells can have a more robust effect on renal tissue regeneration or interruption of AKI and CKD progression. Recently, we have reported the expression of c-Kit cells in kidneys of deceased donors, so future studies are needed to demonstrate the therapeutic potential of these cells in preclinical and human models.

Other approaches to renal regeneration: embryonic stem cells, inducible pluripotent stem cells (iPSCs), organoids and renal decellularisation

Embryonic stem cells and inducible pluripotent stem cells are capable of originating the three types of embryonic layers, giving rise to any cell type when appropriate culture conditions are applied. Modest clinical trials are underway with these cells.

iPSCs have been studied as a model for the re-creation of renal diseases and culture plate, studies of signalling pathways, therapeutic tests, drug screening, and the generation of renal and organoid progenitors that can be used for renal regeneration and for a better understanding of the pathways involved in renal development and pathological processes. Other robust platforms that can be used for this purpose include 3D printing techniques and kidney-on-a-chip microfluidic technology. Renal decellularisation presents a therapeutic alternative and its use has already been successfully tested in small animals, combined with recellularisation with endothelial cells, renal foetal cells and MSCs. Renal decellularisation studies in larger animals are needed, and in the future, kidney from pigs or from expanded criterion donors may be used as an alternative or as a bridge to kidney transplantation.

CHALLENGES TO CELL THERAPY

Heterogeneity of AKI causes.

Each scenario promotes a type of molecular signature, requiring specific interventions for each in order to regain homeostasis. Understanding the biological environment in which cells are being inserted is extremely important in order to design the best approach beforehand and to understand possible therapeutic outcomes after therapy.

High structural complexity of kidneys.

The kidneys are formed from two germinal foci, the ureteric bud and the metanephric mesenchyme, which differ in more than 30 different cell types in the adult kidney. Thus, an intense association between epithelium and vascular tissue is formed in various functions for hemodynamic balance and electrolyte balance.

Complicating factors of MSCs therapy itself

Exact understanding of the type of cell used

The acronym “mesenchymal (stromal) stem cell” refers to a diverse set of cell types and is therefore it is inaccurate. From the moment of cell extraction to the choice of tissue source, they already interfere with potential, function and transcripts.
Administration timing

Ideally, MSCs should be injected at the very beginning of AKI changes. The difficulty of this moment is the silent form of the lesion, without presenting typical symptoms. Good biomarkers should be established to identify as soon as possible the onset of AKI, quickly and early. Once this ideal moment of action is identified, it is necessary to have the cells ready for injection, requiring very well structured logistics and making it difficult to use autologous cells (due to the time of preparation and expansion in culture).

Compatibility between injected cells and receptors

Despite the well-established notion of MHC-II expression by MSCs, further understanding of the mechanisms related to the immune privilege or immunosuppression ability of MSCs is needed, which may be crucial for the successful integration of cells into the patient and the success of the therapy, as it happens in cases of bone marrow transplantation. This knowledge is even more necessary in the clinical setting, which often requires multiple dose applications to achieve the expected outcome in chronic diseases.

In favour of the use of autologous MSCs, a meta-analysis in heart failure patients favour increased exercise capacity, left ventricular ejection fraction, quality of life and reduced mortality and hospital readmission rates. In another meta-analysis, treatment with whole bone marrow autologous cells (dose ranged from 382.6±10⁶ to 2.8±1.9x10⁶) was effective for reducing glycated haemoglobin (HbA1c) by 1.18% and for reducing the need for insulin at 3, 6, 9 and 12 months after treatment.

There is recent evidence that allogeneic MSCs would be as effective as autologous MSCs in improving the final diastolic volume and left ventricular ejection fraction of patients with ischemic cardiomyopathy. Importantly, allogeneic MSCs did not promote immune response at the receptors. In renal transplant patients, injections of autologous and allogeneic MSCs were also considered safe.

Understanding the specific action mechanisms of different MSCs types

There is a lack of skill specification data that MSCs present according to their tissue origin, for the proper adaptation of the cell type to the clinical picture to be applied. Important qualifications of MSCs such as cell-type differentiation of damaged target tissue, immunosuppression and anti-inflammatory action have been tested in vitro and do not necessarily accurately predict actual clinical potency in each scenario. An interesting study has shown that for the immunosuppressive action of MSCs in patients with host disease against donor, cytotoxic immune attack of the host patient against injected MSCs is essential, inducing them to apoptosis. Patients who responded best to therapy were the ones with the highest cytotoxicity against injected MSCs. According to the evaluation of the existing literature, the decision of the moment of injection of the cells determines the microenvironment that they will find. MSCs, in response to the inflammatory microenvironment, activate their own anti-inflammatory mechanisms, defining the resultant patient-cell therapy interaction. This may explain some negative results obtained by clinical trials. For example, patients who received MSCs prior to kidney transplantation showed no difference from the control group in relation to the common adverse effects of the procedure, which can be explained by the microenvironment without the inflammatory IR insult installed and, consequently, the lack of activation of MSCs to the anti-inflammatory pattern.

Monitoring patients beforehand in order to identify these more responsive subgroups and understand the timing of the most appropriate pathogenesis for cell administration is extremely valuable in achieving the desired efficacy of the therapy.

Data from clinical trials are in progress

Most clinical studies are based on safety and efficacy outcomes and are not designed with large numbers of patients and have heterogeneity in injection dose and frequency. However, the occurrence of adverse events after treatment with MSCs does not appear to be different from the control group.

Cell dose per individual: uncertainties

There is a detrimental mismatch between data from preclinical and clinical studies regarding the appropriate amount for cell therapy with MSCs. Commonly, in rodents, the intravenous dose is 50 million/kg/weight. In humans, MSCs are usually transfused around 1-2 million/kg/weight. However, weight adjustment may not be the best measure for comparing humans and rodents for therapeutic perspectives. Even so, considering that they respect the same biological mechanism of action and that the effects are...
dose-dependent, this difference in methodology imposes a negative bias in clinical practice due to the lower dose used in humans.

**Administration route: more effective biodistribution for the desired outcome**

There is still no consensus on the best route of injection of MSCs in preclinical and clinical trials, and the intravenous route is widely used. Depending on the choice, there is a different dynamics of cell distribution in the body, affecting the mechanism of action and possibly the clinical outcome. Among the options, some choices have practical methodological ease in the routine application and also in the transition to clinical use, such as the extravascular (intraperitoneal, intramuscular and subcutaneous) pathways. Testing these pathways, it has already been shown that MSCs, when acting in a systemic manner, also end up benefiting the organ affected by the disease in question, even with the distance

Regulated clean room

It is necessary to define production standards according to the disease and the type of patient. Isolation method, culture time and environment composition can all affect the potency and quality of the final product of MSCs. It is suggested that MSCs be injected until passage (P)2, when the amount of cells obtained is also sufficient. It is still necessary to consider the costs and complexity of these processes, and it is extremely important to evaluate measures that enable large-scale production at low cost, as it is done in the processes of blood transfusion centres.

One of the challenges of cell therapy with MSCs is a better understanding of the occurrence of chromosomal alterations, which, although rare (n=1/152), leads to the disposal of MSCs. Thus, the genomic integrity of MSCs, assessed by karyotype, should always be considered, although the ideal moment, if soon after cell collection, in which passage or before infusion, is still a matter of debate.

Finally, the additional characterization of MSC manufactured products is essential for a better understanding of the phenotypic characteristics and their subpopulations, as well as for the evaluation of their therapeutic potential.

**CONCLUSIONS**

Cellular therapy with MSCs has benefits in preclinical studies of AKI through various mechanisms, such as anti-inflammatory, antiapoptotic, oxidative anti-stress, antifibrotic, immunomodulatory and proangiogenic. Such benefits may also explain many of the positive effects of that therapy on humans.
