Color Doppler of Meckel’s diverticulum: report of two cases*

Divertículo de Meckel ao Doppler em cores: relato de dois casos

Mariana Damian Mizerkowski¹, José Vicente Noronha Spolidoro², Matias Epifanio³, João Cyrus Bastos⁴, Matteo Baldisserotto⁵

Abstract Meckel’s diverticulum is the most common congenital anomaly of the gastrointestinal tract and bleeding is its most frequent complication. Scintigraphy, B-mode and Doppler ultrasonography, and computed tomography may be utilized to detect complications. The present report describes two cases of complicated Meckel’s diverticulum detected at ultrasonography whose findings were different from those described in the literature.

Keywords: Meckel’s diverticulum; Color Doppler; Ultrasonography.

INTRODUCTION

Meckel’s diverticulum (MD) is found in 2–3% of the population and is the most common congenital abnormality of the gastrointestinal tract, and hemorrhage is the most frequent complication.

At B-mode ultrasonography (US), MD appears as a cyst-like, tubular-shaped or tear-drop-shaped structure, with the so called gut signature. Scintigraphy, US and computed tomography (CT) may be utilized for detecting complications.

CASES REPORT

Case 1

A two-year-old boy admitted to the emergency department for painless hematochezia for two days. Laboratory tests demonstrated hemoglobin = 7.6 mg/dl; platelets = 432,000/mm³, without leukocytosis. Clinical examination did not demonstrate any significant alteration.

At B-mode US, a cystic image with gut signature was identified in the lower right abdominal quadrant (Figure 1A). During the examination, the cyst emptied itself after contractions. Parietal thickening of the distal ileum and enlarged mesenteric lymph nodes were observed. Color Doppler US did not demonstrate any sign of hyperemia of the cystic wall (Figure 1B).

The presence of one MD was confirmed by Tc-99m scintigraphy (Figure 1C).

At the fourth day of hospitalization, a MD was localized in the terminal ileum and was resected (Figure 1D). Anatomopathological study of the surgical specimen revealed gastric and enteric mucosa in the MD without inflammation or ulcerations. Three days postoperatively, the patient was uneventfully discharged.

Case 2

A 15-year-old boy presenting blood in stools for one month. Four days after the symptoms onset, the patient underwent rectosigmoidoscopy which revealed the presence of stale blood in the rectosigmoid junction. Serum hemoglobin level was 11 mg/dl. History of appendectomy three years before.

At color Doppler US, a fixed cystic image with gut signature was observed in the right lower abdominal quadrant; with no sign of parietal hyperemia or inflammation (Figure 2A). The Tc-99m scintigraphy was inconclusive. Laparotomy performed in the next day demonstrated a perforated MD at 30 cm from the terminal ileum, attached to the adjacent bowel (Figure 2B).

Anatomopathological study of the surgical...
specimen demonstrated a layer of gastric mucosa with inflammation.

DISCUSSION

Meckel’s diverticulum is a true diverticulum and its layers are formed by all the layers of the ileal wall\(^6\). Ectopic gastric mucosa and pancreatic tissue may be found within the diverticula\(^1,4\). Typically, MD is located in the terminal ileum at 40–100 cm from the ileocecal valve and, for this reason, should be considered in the differential diagnosis of right iliac fossa conditions, such as appendicitis\(^3,7\). It may be asymptomatic and incidentally found at laparotomy. The most common symptom is painless hematochezia\(^4\) and complications include perforation, intussusception and volvulus.

In cases where the MD is inflamed, it may be detected by US, CT or scintigraphy\(^2,7\). Ultrasonography has become a relevant tool in the diagnosis, particularly in emergency cases, considering the symptoms, additionally to the fact that it is a method free from ionizing radiation.

In both cases, the B-mode US demonstrated the MD with a typical appearance of a cystic mass with the so called gut signature: inner hyperechoic layer (submucosal), and outer hypoechoic layer (muscular)\(^2,4\). Such an appearance may mimic intestinal duplication cysts, although the latter ones have a smoother inner layer as they are in the intestinal mucosa\(^2,3\).

Other sonographic feature of inflamed MD is the absence of peristalsis which makes it different from the adjacent bowel loops\(^3\). A hemorrhagic MD may contract itself and complicate its detection, like in case 1, where the MD contracted itself during the examination, remaining completely emptied.

Generally, in an inflamed diverticulum, color Doppler US can detect parietal hyperemia and presence of a nurturing vessel\(^3,4\). In case 2, B-mode and color Doppler US did not show any mural inflammation sign, despite the presence of perforation and the fact the anatomopathological analysis has demonstrated inflammation.

In the investigation of a MD, Tc-99m scintigraphy results may be either negative or inconclusive since they depend on the presence of ectopic gastric mucosa – which may ulcerate and bleed –, and the bleeding rate\(^8\), which justifies an investigation with other imaging methods such as US. In the patient of the case 1, in spite of the presence of hemorrhage, signs of inflammation or ulceration were not found in the surgical specimen analysis.

In case of MD perforation, a hyperechoic outer fibrin layer can be visualized\(^4\). Such image was not demonstrated at the B-mode US in the patient of case 2.

Previous reports on the utilization of color Doppler US in the assessment of MD\(^4\) have shown that hyperemia resulting from inflammation may be detected. The nurturing vessel of the diverticulum can also be identified\(^3,4\). In both cases presently described, color Doppler US did not demonstrate any sign of mural inflamma-
tion, although in one of the cases, with presence of perforation and adhesions, the lesion has demonstrated inflammation at anatomopathological exam.

Ultrasonography is a useful tool in the evaluation of MD, particularly in cases where scintigraphy is negative or inconclusive\(^{(3,6)}\). Meckel’s diverticula without signs of inflammation can be detected because of their typical presentation of a cystic mass with walls structured like the bowel’s (gut signature) with possible peristalsis. Data available in the literature\(^{(3,4)}\) indicate that in MD the inflammatory process is identified at color Doppler US by the increase in the vascularization of such structure. In the present cases, the absence of signs of hyperemia was observed even with a perforated and inflamed MD. The authors cannot explain such a fact. Further studies with a higher number of patients could provide more information for determining the color Doppler US accuracy in the identification of MD inflammation.
