A male, 50-year-old with hypogonadotropic hypogonadism and anosmia was assisted in the Unit of Endocrinology of Hospital Universitário Antonio Pedro, being submitted to magnetic resonance imaging of the head and sella turcica (Figures 1 and 2).

In 1982, the patient who, at that time was 21-year-old, sought the Public Endocrinology Service and was submitted to laboratory tests with the following results: basal LH level = 10.0 mIU/ml (prepubertal reference values: 2.0–12.0 mIU/ml); basal FSH level = 2.0 mIU/ml (prepubertal reference values: 2.0–12.0 mIU/ml); testosterone = 38.0 ng/dl (reference values: 245–1600 ng/dl); prolactin = 10 ng/ml (reference values: 0–25 ng/ml); LHRH stimulation test demonstrated isolated LH deficiency; clomiphene stimulation test with absence of response; 46,XY karyotype; besides estimated bone age corresponding to 15 years; azoospermia; normal cranial radiography; normal computed tomography of the sella turcica; and normal whole abdomen ultrasonography.

Figure 1. Magnetic resonance imaging of sella turcica – contrast-enhanced, sagittal, T1-weighted image.

Figure 2. Magnetic resonance imaging – coronal, T1-weighted (A) and T2-weighted (B) images.
Images description

Figure 1. Magnetic resonance imaging of sella turcica. Contrast-enhanced, sagittal, T1-weighted image demonstrating normal hypophysis and hypophyseal stalk.

Figure 2. Magnetic resonance imaging. Coronal, T1-weighted (A) and T2-weighted (B) images demonstrate absence of olfactory bulbs.

Diagnosis: Kallmann syndrome.

COMMENTS

Kallmann syndrome is a rare neuroendocrine disorder characterized by hypogonadotrophic hypogonadism associated either with anosmia or hyposmia. The incidence of such a condition corresponds to 1:10,000 men and 1:50,000 women. The present diagnostic challenge presents a patient with clinical signs of Kallmann syndrome who was assessed by magnetic resonance imaging, demonstrating absence of olfactory bulbs and sulci with unaltered hypophysis which constitute the typical findings corroborating the diagnosis of this disease.

At magnetic resonance imaging, the olfactory bulbs are better visualized in the coronal plane, as structures adjacent to the cribriform plate, and the olfactory sulci are seen between the straight gyrus and the medial orbital gyrus. The patient assessment reveals typical findings of Kallmann syndrome. Such characteristic image, in association with clinical findings, determines the definite diagnosis of Kallmann syndrome, as well as the differential diagnosis with idiopathic hypogonadotropic hypogonadism. In cases of non-classical presentation or disorder in prepubertal children in which the clinical findings are still to be integrally established, magnetic resonance neuroimaging, in association with genetic investigation, is a key method in Kallmann syndrome presumption. A correct imaging, especially in the coronal plane, is of paramount importance, considering the subtlety of alterations which may go unperceived, thus the radiologist should establish a clinical/laboratory correlation with imaging findings.
