Inflammatory myofibroblastic tumor in the larynx

INTRODUCTION

Inflammatory myofibroblastic pseudotumors were initially described in the lung, only then to be identified in various extrapulmonary sites¹. In the head and neck, this disease is more frequently found in the paramosal sinuses, and has already been described in the orbits, palate tonsils, ears, gingiva, pterygomaxillary space, and periodontal tissues. It will rarely involve the larynx. Only twenty-two cases of inflammatory myofibroblastic pseudotumor in the larynx have been described in the indexed literature²,³.

This paper aims to describe a rare case of laryngeal inflammatory myofibroblastic pseudotumor and discuss its diagnostic and therapeutic aspects.

CASE REPORT

J.G., male, 22 years-old, complained about having persistent hoarseness for two months. He claimed not to smoke, abuse his voice, or use medication, and had no gastroesophageal complaints or allergies. Videolaryngoscopy revealed redness and edema on the right vocal fold and a polyoid lesion (Picture 1A). The patient was referred to laryngeal microsurgery to have the lesion removed. Pathology tests indicated the polyoid lesion was covered by a non-keratinizing, squamous epithelium, with a chorion with fusiform cells resembling fibroblasts or myofibroblasts, rarely with a histiocytic aspect, with prominent chronic inflammatory infiltrate rich in plasmacytes, and polymorph nuclei (Picture 1B). Immunohistochemistry tests showed diffuse positive results for 1A4 smooth muscle actin, and results for vimentin and focal positive immunohistochemistry showed diffuse positive for 1A4 smooth muscle actin, and results for vimentin and focal positive immunohistochemistry showed diffuse positive for 1A4 smooth muscle actin, and results for vimentin and focal positive.

Videolaryngoscopy revealed a relapsing polyoid lesion. Another surgical procedure was carried out and the polypl was removed without expanding the surgical margins. Pathology tests confirmed the presence of inflammatory myofibroblastic pseudotumor. The patient has not had any voice-related complaints for 12 months, and his videolaryngoscopy has been normal ever since.

DISCUSSION

Laryngeal inflammatory myofibroblastic pseudotumors represent a rare disease. It was first described in 1992, and is possibly a challenging condition from the diagnostic point of view⁴. The lesion looks clinically suspicious and, histologically, it mimics squamous cell carcinomas⁵. The nature of this disease is still uncertain. Inflammatory myofibroblastic pseudotumors were initially considered to be a non-tumor lesion, being possibly associated with abnormal inflammatory response⁶. Today, this condition is seen as a neoplasm due to the following characteristics: potential for relapsing locally, development of non-adjacent multifocal tumors, infiltrative local growth, vascular invasion, and even distal metastasis. Histologically speaking, the lesions are quite similar to malignant tumors (squamous cell carcinoma, leiomyosarcoma, malignant histiocytoma), and require complementary immunohistochemistry tests⁶.

Laryngeal inflammatory myofibroblastic pseudotumors are extremely rare, with only 22 cases described in the literature⁵. Eighty percent of the patients have this laryngeal disease on their vocal folds. The most common symptoms are apparently hoarseness and dysphonia. Under videolaryngoscopy the lesion is often pedunculated, with a polyoid aspect, but may also present itself as a nodular elevation. Size varies between 0.4cm and 3.5cm. Prognosis is yet unclear, but appears to be favorable as few are the cases of local relapse and complications reported⁶.
