ABSTRACT

Interventions focusing on education and self-management of rheumatoid arthritis (RA) by the patient improves adherence and effectiveness of early treatment. The combination of pharmacologic and rehabilitation treatment aims to maximize the possibilities of intervention, delaying the appearance of new symptoms, reducing disability and minimizing sequelae, decreasing the impact of symptoms on patient’s functionality. Occupational therapy is a health profession that aims to improve the performance of daily activities by the patient, providing means for the prevention of functional limitations, adaptation to lifestyle changes and maintenance or improvement of psychosocial health. Due to the systemic nature of RA, multidisciplinary follow-up is necessary for the proper management of the impact of the disease on various aspects of life. As a member of the health team, occupational therapists objective to improve and maintaining functional capacity of the patient, preventing the progression of deformities, assisting the process of understanding and coping with the disease and providing means for carrying out the activities required for the engagement of the individual in meaningful occupations, favoring autonomy and independence in self-care activities, employment, educational, social and leisure. The objective of this review is to familiarize the rheumatologist with the tools used for assessment and intervention in occupational therapy, focusing on the application of these principles to the treatment of patients with RA.

Introduction

Rheumatoid arthritis (RA) is a systemic autoimmune disease characterized by impairment of the peripheral joints, especially hands and feet. A prevalence of up to three times higher among women is observed, with increasing incidence after the age of 25 years, with greater involvement of populations between 35 and 55 years.

Although there is no consensus on the etiology of RA, it is observed that the combination of inflammation and synovial hypertrophy favor cartilage and bone destruction, promoting joint damage and instability, predominantly affecting the joints of the wrist and metacarpophalangeal and proximal interphalangeal joints of upper limbs. For these reasons, the treatment of patients diagnosed with RA should be started as soon as possible, aiming to reduce the inflammatory activity of the disease and even to obtain remission of symptoms.

Despite advances in the pharmacological treatment achieved in the last 30 years, especially with the advent of disease-modifying anti-rheumatic drugs (DMARDs), the chronicity of RA implies interventions aimed to the education and self-management of the disease to favor the treatment, increasing the adherence and effectiveness of an early approach.

The combination of drug treatment and rehabilitation therapy aims to maximize the possibilities of intervention, delay the onset of new symptoms, reduce disability, minimize sequelae and diminish the impact of symptoms on functionality of the patient.

Occupational therapy (OT) is a health care profession which aims at improving the performance of activities by the patient, providing a means for the prevention of functional limitations, adaptation to lifestyle changes and maintenance or improvement of his/her emotional state and social participation.

The aim of this review is to familiarize the rheumatologist with the assessment and intervention tools used in occupational therapy, focusing on the application of these principles to the treatment of patients diagnosed with RA.

Multidisciplinary treatment – practice of occupational therapy

Due to the characteristic joint impairment of RA, the functionality of the patient is reduced not only by the painful condition, but also by those motor constraints associated. The difficulty in performing daily tasks is one of the main complaints of patients with the disease causing restrictions in most of their areas of performance: from simple activities related to self-care and home maintenance to complex work tasks, the patient presents limitations in doing many of his/her activities of daily living (ADLs).

It is observed that such restrictions affect not only the performance of the activities independently and autonomously, but has a negative impact on the emotional state, social relationships and quality of life of the patient.

Given the participation constraints and the importance of engaging in productive activities for the maintenance of physical and psychosocial health of this population, the occupational therapist is an integral part of the multidisciplinary team of care for patients with RA, being concerned with the performance of ADLs and the inclusion of the patient in meaningful occupations for his/her everyday life.

Due to the multiplicity of involvements motivated by the disease and the singularity represented by the daily activities

<table>
<thead>
<tr>
<th>Assessment tool</th>
<th>Objective</th>
<th>Data collection method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Disabilities of Arm, Shoulder and Hand (DASH)</td>
<td>Measures the level of functional impact resulting from the impairment of the upper limb to perform activities of daily living related to self-care, mobility, home maintenance and recreation. The device has optional modules specific to assess the impairment of work activities and the practice of sport and musical activities.</td>
<td>Structured, self-administered questionnaire. Score from 0 to 100 points, indicating increasing disability due to involvement of upper limbs.23,24</td>
</tr>
<tr>
<td>Sequential Occupational Dexterity Assessment (SODA)</td>
<td>Assesses the patient's performance on twelve tasks, performed unilaterally and bilaterally, including writing, handling objects and pieces of clothing and hand hygiene.</td>
<td>Structured test. Scored by the therapist, according to the patient's performance on the tasks described.25,26</td>
</tr>
<tr>
<td>Health Assessment Questionnaire (HAQ)</td>
<td>Measures the level of functionality based on the difficulty reported by the patient to perform activities in eight areas, including reaching, self-care, mobility and object holding.</td>
<td>Standardized questionnaire consisting of 20 questions, scored from 0 to 3, indicating increasing disability.27,28</td>
</tr>
<tr>
<td>Canadian Occupational Performance Measure (COPM)</td>
<td>Assesses the patient's perception of the importance of ADLs in self-care, productivity and leisure areas, as well as his/her satisfaction on the implementation and performance of these tasks.</td>
<td>Qualitative questionnaire in a format of semi-structured interview. Provides two scores (for performance and satisfaction), allowing the patient's pre- and post-intervention evaluation.29,30</td>
</tr>
<tr>
<td>Handgrip dynamometry – JAMAR® Dynamometer</td>
<td>Assesses handgrip strength by measuring the maximum force exerted by the patient when pressing a hydraulic dynamometer.</td>
<td>Standardized test, measured in pounds or kg/F. Requires standardization of postures and grip forms utilized during the evaluation.31,32</td>
</tr>
<tr>
<td>Digital pinch dynamometry – Pinch Gauge® Dynamometer</td>
<td>Measures the digital pinch strength of the patient with three types of tweezers, using the fingers I, II and III, representing both fine movement (opposition between fingers I and II) and grip strength (lateral grip).</td>
<td>Standardized test, measured in pounds or kg/F. Requires standardization of postures and grip forms utilized during the evaluation.33,34</td>
</tr>
<tr>
<td>Manual Dexterity and Function Testing</td>
<td>Measure manual dexterity through the manipulation of objects and utensils common to ADLs. Examples: Jepsen–Taylor function test, Purdue Pegboard, O’Connor Finger Dexterity.</td>
<td>Standardized tests, generally using as a parameter for evaluation the time required for manipulation of objects during the course of systematic tasks.35</td>
</tr>
<tr>
<td>Hospital Anxiety and Depression Scale (HADS)</td>
<td>Evaluates the occurrence of symptoms of anxiety and depression among patients.</td>
<td>Standardized questionnaire containing seven questions to assess anxiety and seven for depression, scored from 0 to 3. The final score is the sum of the points; results &gt;7 suggest states of anxiety and/or depression.18</td>
</tr>

for each patient, the first step toward the realization of an effective therapeutic intervention is to obtain relevant data on the state of the disease and its impact on the patient’s ADLs. The evaluation is an ongoing process, which enables the monitoring of treatment and the interventions needed, as well as the modification of these during periods of exacerbation and remission.21

Assessment in occupational therapy

The evaluation aims at obtaining data relating to the physical, emotional and social state of the patient, as well as the impact of the disease on his/her ADLs, providing objective data on the patient’s occupational performance that allow monitoring of his/her evolution during treatment.22

Historically, occupational therapists combine the use of semi-structured interviews and standardized tools for gathering information to enable the establishment of a baseline for the therapy: disease status and functional limitations, expansion of the understanding of the contexts of a patient’s life, identification of his/her priorities, monitoring of the disease and the effectiveness of proposed interventions.21 The selection of assessment methods should take into consideration the main complaints of the patient and their relevance to the clinical presentation.23 Table 1 illustrates some of the standardized assessment tools that comprise the evaluation of patients with RA by the occupational therapist.

Independent of the choice of instruments for assessment, is important that the information obtained is related to the occupational performance of the patient, i.e., the data must aim not only to measure the intensity of a particular symptom...
(fatigue, pain, functional capacity), but also the influence of this on the patient’s ability to engage and perform tasks relevant to his/her day-to-day.\textsuperscript{12,21}

**Interventions of occupational therapy**

**Patient guidance and education – changing habits to cope with illness**

The transmission of knowledge and the understanding of the patient about his/her condition do not guarantee, by itself, any change of attitudes necessary for the management of complications arising from a chronic disease; so that OT has as main objective the voluntary change of habits, extended to all areas of the patient’s performance and not only to those activities afflicted by pain or biomechanical imbalances driven by the disease.\textsuperscript{24}

The multidisciplinary interventions for patients with RA aim to control pain and fatigue, aiming their functional improvement by combining different modalities of treatment.

Among some of the interventions focused on patient adjustment and empowerment concerning the disease, the techniques of joint protection and energy conservation are examples of changes in habits, by the way of conducting ADLs, which promote changes not only on functional capacity, but also on the psychological well-being, personal control and self-acceptance – fundamental concepts for improving the quality of life of the patient.\textsuperscript{34}

**Joint protection and energy conservation**

Joint protection techniques are a set of guidelines and preventive strategies used in the management of pain and fatigue,\textsuperscript{75} associated with other symptoms in patients with RA, which aim to apply ergonomic and biomechanical principles while performing ADLs to protect joint structures of normal and abnormal forces that may contribute to the installation of deformities or aggravate deformities already present.\textsuperscript{36,37}

This approach was first described in 1965,\textsuperscript{38} through the analysis of motor impairments motived by the inflammatory process common to RA and its combination with biomechanical principles, aiming to minimize the action of forces that favored the development of joint deviations and deformities during performing daily tasks,\textsuperscript{39} for example, hyperextension of the metacarpophalangeal joint of the finger I, ulnar deviation of metacarpophalangeal joints of the fingers II–V and installation of deformity standards, such as swan neck, hammer toe or buttonhole toe, through involvement of distal interphalangeal joints.\textsuperscript{50}

Due to the importance and constancy necessary for the accomplishment of ADLs, modifications in their performance allow a significant reduction in joint stress and energy expenditure, facilitating or enabling the participation of the patient in meaningful occupations.\textsuperscript{36,37} Table 2 illustrates the main guidelines of the concepts of joint protection and energy conservation.

<td>Modify the environment according to practices of joint protection and ergonomics</td>
</tr>
</tbody>
</table>

By modifying work methods and environments, use of assistive devices (assistive technologies) and inclusion of breaks in the routine, the objective here is the reduction of pain at rest and during movement, by minimizing nociceptive stimuli on the inflamed joint capsules, decreasing the force incident on the joints and controlling energy expenditure during daily activities, enabling joint preservation and improvement or maintenance of the patient’s functionality.\textsuperscript{41}

Moreover, conducting activities to strengthen the perartic- ular muscles and maintain joint range of motion, especially in the upper limbs, are also resources that contribute to the maintenance or improvement of the patient’s functional capacity,\textsuperscript{42,43} allowing a better performance and preservation of joint structures impaired by RA.

Practical examples of some of the techniques of joint protection and energy conservation\textsuperscript{44} are illustrated in Fig. 1.

Randomized trials with high levels of evidence on the effectiveness of methods of joint protection and energy conservation showed significant improvement with respect to pain reduction among patients receiving the guidelines for changes in their ADLs.\textsuperscript{45–47} Improvement in fatigue and increased social participation,\textsuperscript{47} reduction of morning stiffness, lower incidence of deformities in the hands\textsuperscript{48} and improved functionality\textsuperscript{49} were observed, even among patients with severe RA state.\textsuperscript{50}

**Modifying activities and work environments**

Although most functional assessments have focused on the difficulty presented by the patient while performing self-care and mobility activities, dysfunctions related to work activities represent a serious consequence of RA.\textsuperscript{51}

The rate of retirement for reasons related to RA can vary from 7% of cases in the first year after diagnosis up to 39% of patients with over 15 years of diagnosis in the absence of treatment targeted to labor difficulties\textsuperscript{51}; with respect to North American and European populations, is expected that up to
joint positioning during activity, replacement of fixtures by other of smaller weight or with better handgrip\textsuperscript{57} and guidance on stress management and acquisition of strategies (coping) to handle with the workload.\textsuperscript{58}

Although some review studies show no high level evidence on the effectiveness of specific ergonomic interventions to reduce problems related to upper limbs,\textsuperscript{59} there is satisfactory evidence to support such interventions with respect to patients with RA,\textsuperscript{57} suggesting improvement in functionality, pain and satisfaction with the work in the long term, when compared to individuals who did not get these interventions.

**Assistive technologies – orthotics and adaptations**

The concept of assistive technology includes devices, guidelines and practices that aim to maintain, enhance or facilitate the performance of self-care, instrumental, educational, employment or social activities.\textsuperscript{60}

Among the range of instruments available to patients with RA, the adaptations of utensils and the use of orthotics are some of the major resources to promote improved grip, biomechanical alignment and joint stress reduction, as well as to allow the development of activities and occupations, contributing to the patient’s functionality and autonomy.\textsuperscript{51}

The adaptation of utensils requires a thorough analysis of the activity performed by the patient, in order to determine what are the main challenges encountered and possible solutions to be proposed. Such modifications may include from changes in the way of conducting the activity (such as guidance on joint protection and energy conservation) to changes in the shape, weight and size of utensils.

Thicker handles and adaptations to facilitate or replace the handgrip strength, for example, elastic or neoprene strips, favor the handling of cutlery, writing instruments and personal hygiene materials, such as toothbrushes and hair combs.

The replacement of drinking glasses for mugs, the use of modified cutting boards, soap and detergent dispensers and clotting adaptations are examples of simple devices which promote important functional changes to the patient.\textsuperscript{62–64}

Examples of adaptations to promote improvement in performing ADLs are illustrated in Fig. 2.

Orthoses (splints) are resources used by therapists to promote better joint support, reduce pain and optimize functional performance of the patient.\textsuperscript{55} Although several models are available, clinical reasoning used for prescribing an orthosis involves the needs for each case; the same orthosis can be prescribed for multiple objectives.

Among the most common indications, pain control, decreased morning stiffness, mechanical support for joints, encouragement of joint motion and functionality, and certain postoperative situations (where the combination of joint alignment, immobilization and application of traction forces is required) can be cited.\textsuperscript{65–68} Some models of orthoses commonly indicated are illustrated in Fig. 3.

Although to date there is no conclusive evidence on the effectiveness of orthoses for improved functionality and handgrip strength,\textsuperscript{65} some studies suggest that the use of orthotics for hands and wrists positioning during inflammatory phases

---

Fig. 1 – Examples of modifications in performing activities of daily living. The items on the left indicate movement patterns in which the position of the joints of the wrist and fingers enhance mechanical forces toward deformities commonly observed among patients with RA. The illustrations on the right suggest modifications that favor the use of other, more stable, joints, or the distribution of the load among multiple joints, avoiding painful and potentially harmful positions.

One third of patients will abandon the work during the first three years of the disease.\textsuperscript{52}

Abandonment of employment is a last resort, face to the limitations encountered by patients with RA: before retirement, increases of stress levels, job changes, restrictions on workload, loss of promotion opportunities and greater frequency of absenteeism and of job changes are observed more often among this population.\textsuperscript{53} It is estimated that the reduction in productivity motivated by RA caused losses of approximately 7000 Euros/year per patient,\textsuperscript{54} and up to 25% of the working period may be affected by conditions related to the disease.\textsuperscript{55}

The early treatment conducted by a multidisciplinary team is an effective method to minimize complications related to work, maintaining the work capacity of these patients for a period of time similar to that found among the healthy population.\textsuperscript{51,55}

Given the multiplicity of situations and perceptions about work activity reported by patients, individualized strategies are indicated as the best approach to labor difficulties, including a specific evaluation of the situation and of the workplace.\textsuperscript{52}

Changes for a better performance of the activity may include the organization of the tasks that compose the work activity, changing shifts, and a fair division of the workload throughout the day;\textsuperscript{56} ergonomic modifications such as new furniture and changes in the workplace, ensuring a proper
promote improvement in pain and morning stiffness for the patient.68,69  
Braces used for stabilization of the interphalangeal joints also exhibit significant levels of evidence in reducing pain, although no significant changes on hand function or strength during its use have been observed.70

Conclusions

Due to the systemic nature of RA, a multidisciplinary follow-up is necessary for the proper management of the impact of the disease on various aspects of life of the patient. As a member of the health team, the occupational therapist aims to improve and maintain his/her patient's functional capacity, preventing the worsening of deformities, aiding in the process of understanding and coping with the disease, and providing means for carrying out the activities required for the engagement of the individual in meaningful occupations, contributing to his/her autonomy and independence in self-care, labor, educational, social and leisure activities.

It is important that the rheumatologist become aware of the general principles of therapy, so that he/she can suggest their use more consciously, as an additional tool in the treatment of patients diagnosed with RA.
