**Candida ESOPHAGITIS: SPECIES DISTRIBUTION AND RISK FACTORS FOR INFECTION**

Dimas Alexandre KLIEMANN(1), Alessandro Comarú PASQUALotto(1,2), Maicon FALAVIGNA(3), Thiane GIARETTA(4) & Luiz Carlos SEVERO(1,4,5)

**SUMMARY**

Although *Candida albicans* is the main cause of fungal esophagitis, other species such as *C. tropicalis, C. krusei* and *C. stellatoidea* have also been implicated. Several studies have identified risk factors for *C. albicans* esophagitis. However, data for non-*C. albicans* species is still sparse. The aim of this study was to determine the etiology of *Candida* esophagitis in our medical centre over an 18-month period. Additionally, we aimed to investigate predisposing conditions for esophageal candidosis caused by different *Candida* species. A total of 21,248 upper gastroscopies were performed in Santa Casa Complexo Hospital between January 2005 and July 2006. The prevalence of *Candida* esophagitis was 0.74% (*n* = 158). *C. albicans* caused the vast majority of infections (96.2%), followed by *C. tropicalis* (2.5%), *C. lusitaniae* (0.6%) and *C. glabrata* (0.6%). There were 81 women (51.3%) and 77 men (48.7%). No case of mixed infection occurred. Concomitant oral candidosis was documented for 10.8% (*n* = 17). Most of cases (55.1%) involved outpatients. Around one fifth of patients in our cohort had no identifiable risk factors for esophageal candidosis (20.8%). Since nearly all infections were caused by *C. albicans* we were not able to determine risk factors for esophagitis caused by other *Candida* species.

**KEYWORDS:** Candida; Opportunistic infections; Esophagitis; Endoscopy; Risk factors; Yeasts.

**INTRODUCTION**

*Candida* species are the most common agents of fungal esophagitis. While this is usually caused by *C. albicans*10, other species such as *C. tropicalis, C. krusei* and *C. stellatoidea* have also been involved16. Risk factors for *Candida* esophagitis have been documented in several series. These include pharmacological suppression of gastric acid production12,13, use of antibiotics24,26, previous vagotomy3, functional or mechanical esophageal abnormally3,8, and endocrine diseases such as diabetes mellitus, hypothyroidism and hyperparathyroidism11,12. Malnutrition, alcoholism, advanced age20,27,28, and therapy with corticosteroids - either systemic or inhaled - has also been implicated19. However, there are very limited data from Brazilian patients. In addition, very little is known for infections caused by species other than *C. albicans*. This study aims to document the species distribution in patients with *Candida* esophagitis over an 18-month period (2005-2006) in a single medical centre. We were particularly interested in the comparison of risk factors for esophageal candidosis amongst patients infected by different *Candida* species.

**MATERIAL AND METHODS**

This study was performed between January 2005 and July 2006 at Santa Casa Complexo Hospital, an university tertiary hospital with 1,200 beds located in Porto Alegre, Southern Brazil. Esophageal candidosis was defined by the recovery of *Candida* species from either esophageal brushing or a biopsy of the esophagus performed during upper gastroscopy. Esophageal candidosis was endoscopically confirmed in the presence of typical sparse or coalescent white plates covering the esophageal mucosa. Only cases of endoscopically-confirmed *Candida* esophagitis were included, so patients considered to be only colonized by *Candida* species were excluded. Since this was a retrospective study, neither clinical symptoms nor reason for performing endoscopy was evaluated. All samples obtained endoscopically were sent in saline solution to the Mycology laboratory. The germ tube test was used to differentiate *C. albicans* from other *Candida* species, which were in turn identified with ID 32C (bioMérieux Marcy l’Étoile, France).

Medical records of patients with *Candida* esophagitis, were reviewed to identify potential risk factors for the infections, presented in the 30 days preceding the endoscopic procedure. Chronic therapy with corticosteroids was considered when patients were in use of 20 mg of prednisone of equivalent for >14 days.

Statistical analysis was performed with SPSS software. Categorical variables were compared using the chi-square and the Fisher’s exact tests, and *p* values ≤ 0.05 were considered statistically significant. The study received ethical approval by the hospital’s research ethic board (protocol number1000/05).
RESULTS

During the period of study 21,248 upper gastrointestinal endoscopies were performed in our medical centre. The prevalence of fungal esophagitis was 0.8% (n = 163). Five patients were excluded - four due to lack of clinical data and one because the infection was caused by *Saccharomyces cerevisae*. The vast majority of infections for the remaining 158 patients were caused by *C. albicans* (96.2%), followed by *C. tropicalis* (2.5%), *C. lusitaniae* (0.6%) and *C. glabrata* (0.6%). There were 81 women (51.3%) and 77 men (48.7%). All patients were adults, with ages ranging from 21-88 years old (mean 57.4; standard deviation 16.7 years). No case of mixed fungal infection occurred. Concomitant oral candidosis was documented for 10.8% (n = 17). Most of cases (55.1%) involved outpatients.

The majority of patients (79.2%) had at least one identifiable risk factor for esophageal candidosis. Median number of risk factors per patient was 1.0 (range, 1-6). As shown in Table 1, no difference was observed in the distribution of risk factors for esophageal candidosis when *Candida* species were considered.

DISCUSSION

The prevalence of fungal esophagitis in this study involving 21,248 patients submitted to upper gastrointestinal endoscopy was 0.77%. Similar frequencies have been reported in other series. We observed in our study that virtually all cases of fungal esophagitis were caused by *Candida* species, with one rare case due to *S. cerevisae*.

Although esophageal candidosis is a common opportunistic infection in patients infected by the human immunodeficiency virus (HIV), the vast majority of patients in our series (93.7%) were not infected by this virus. Since this was a retrospective study, the importance of this variable might be underestimated. However, other authors have demonstrated a marked reduction in the prevalence of esophageal candidosis in HIV patients over the last decade, justified by the immunological benefit obtained from antiretroviral therapy.

Around one fifth of patients in our cohort had no identifiable risk factors for esophageal candidosis (20.8%). It has been demonstrated that esophageal candidosis can occur in healthy individuals. Still the mechanisms of infection in these patients are not clear. *Candida* species are known to colonize the esophagus of 20% of healthy adults. In the series by MIMIDIS et al., 36% of patients had no evident risk factor for esophageal candidosis. Interestingly, we observed that 50% of patients infected by species other than *C. albicans* showed no evident predisposing condition for the infection. Due to the limited number of patients with non-*C. albicans* infection (n = 6), we were not able to show any difference of statistical significance. The clinical or biological importance of this, however, is unknown. In addition it should be noted that, due to the retrospective nature of our study, some data may be missing. In particular, immunological or endocrine conditions predisposing patients to chronic mucocutaneous candidosis were not systematically investigated.

In conclusion, we found *C. albicans* to be the main etiology of fungal esophagitis in our medical centre. Most of patients had one evident predisposing condition for *Candida* esophagitis, and HIV infection was quite uncommon. The occurrence of non-*C. albicans* infections in patients with no obvious risk factors for these conditions deserves further investigation.

RESUMO

Esofagite por *Candida*: distribuição da espécie e fatores de risco para a infecção

Embora *Candida albicans* seja a principal causa de esofagite fúngica, outras espécies como *C. tropicalis*, *C. krusei* e *C. stellatoidea* também têm sido implicadas. O objetivo desse estudo foi descrever espécies causadoras de esofagite fúngica em nosso centro durante um período de...
18 meses, além de comparar condições predisponentes para candidose esofágica causadas por diferentes espécies de Candida. De janeiro de 2005 a julho de 2006, 21.248 endoscopias digestivas altas foram realizadas no Complexo Hospitalar Santa Casa (Porto Alegre, Brasil). A prevalência de esofагite por Candida foi de 0,74% (n = 158). C. albicans foi a causadora da maioria das infecções (96,2%), seguida por C. tropicalis (2,5%), C. lusitaniae (0,6%) e C. glabrata (0,6%). Candídeo oral concomitante foi documentada em 10,8% (n = 17). Cerca de 21% dos pacientes não teve qualquer fator de risco identificável para candidose esofágica. Em função do pequeno número de pacientes infectados por espécies não-Candida albicans, não foi possível determinar fatores de risco para estas infecções.
