Objective
This study aimed to evaluate the influence of nutritional status on the quality of life of a cohort of cancer patients submitted to chemotherapy.

Methods
Patients receiving chemotherapy for the first time in a University Hospital in Pelotas (RS), Brazil, were evaluated prospectively. Their nutritional risk was determined by the Patient-Generated Subjective Global Assessment scores and their quality of life by the World Health Organization’s quality of life questionnaire, administered at the beginning and end of the study.

Results
One hundred and forty-three patients were studied, 76.2% being females. The prevalence of malnutrition at baseline was 14.0%. The present study found that malnourished patients had a poor quality of life. The nutritional risk of 41.6% of the patients increased after chemotherapy. A significant association was found between the presence of symptoms and increased nutritional risk (p<0.001). Additionally, there was a significant negative correlation between physical domain and nutritional risk scores, showing that quality of life increases as nutritional risk decreases.

Conclusion
Nutritional risk is inversely associated with quality of life in cancer patients after chemotherapy. Early nutritional interventions could minimize the side effects of treatment with a positive impact on quality of life.

---

**INTRODUCTION**

Malnutrition in cancer patients is frequently reported in the literature and found in almost 75% of the patients at diagnosis. It is also significantly associated with increased morbidity and mortality, reduced response and tolerance to treatment, higher costs, diminished chances of survival and worse Quality Of Life (QOL)\(^2\). Malnutrition is caused by several factors and may vary according to the type of tumor, its stage and treatment used\(^2,4,5\).

Chemotherapy (CT) is a common cancer treatment and can affect the nutritional status of cancer patients. This effect may be due to the toxicity of the treatment, since traditional chemotherapeutic drugs are nonspecific, attacking healthy cells in addition to diseased cells, and setting off adverse effects that impact nutritional status, such as nausea, vomiting, constipation, diarrhea and others\(^2,4,7\).

Cancer, like other serious illnesses, may cause many changes in a person’s life and the possible confrontation with imminent death may induce metabolic and lifestyle changes which may have a huge impact on QOL\(^8\).

The term “quality of life” has been defined by the World Health Organization (WHO) as the way an individual perceives his or her position in life, the cultural context and system of values he or she experiences in relation to his or her goals, expectations, standards and concerns\(^10\).
Nutritional status and cancer treatment interact in a complex way and have a significant impact on QOL8,9. Although nutritional status during CT is one of most importance, few studies have addressed its impact on the QOL of cancer patients11.

Hence, the aim of this study is to evaluate the influence of nutritional status on QOL in a cohort of patients undergoing CT.

M E T H O D S

This study is a partial analysis of a longitudinal study done at the University Hospital of the Federal University of Pelotas (RS), Brazil which prospectively evaluated all patients aged 18 years or older undergoing CT for the first time between March 2004 and July 2005.

Gender, age, race, marital status, socioeconomic and anthropometric data were collected. The socioeconomic level was classified according to the Brazilian Association of Research Organizations (ABEP) criteria12 which investigates the ownership of appliances and other durable goods, presence of maids and education level of the head of the household. The resulting socioeconomic level varies from class A (richest) to class E (poorest).

Data on the diagnosis, type of CT and disease stage were obtained from the hospital's database. Staging allows one to estimate the probability of survival and plan the treatment13.

Nutritional status was assessed by the Patient-Generated Subjective Global Assessment (PG-SGA), through the administration of a questionnaire modified by Ottery14. This assessment tool is an adaptation of the Subjective Global Assessment (SGA) developed by Detsky15. Its main purpose is to provide a numerical score for nutritional risk - higher score means greater risk - indicating the level of nutritional intervention required. It is also possible to use the PG-SGA to classify nutritional status into three categories: A (well nourished), B (moderately or possibly malnourished) and C (severely malnourished)14.

The patients were weighted with a Filizola digital scale model PL 150 (150kg capacity, 100g precision) and measured with a 200 cm height rod (1mm precision) attached to the scale.

Quality of life was determined by the WHOQOL-BREF questionnaire. This is a short Portuguese version of the WHOQOL-100. It contains 26 questions grouped into four major domains (physical, psychological, social relations and environmental) and two general questions on overall QOL and general health status. The answers were given using a five-point Likert-type scale and were then converted into scores ranging from 0 to 100. Higher scores indicate better QOL16,17.

The QOL questionnaire was administered and nutritional status assessed on two different occasions: before the first CT cycle and before the last CT cycle.

Statistical analysis was done by the Stata 9.2 statistics package (StataCorp, Texas, USA). The Shapiro-Wilk test was used to verify the normality of the variables. Descriptive analysis was used to determine the means and respective standard deviations of the variables with normal distribution. A paired Student’s t-test was used to compare the means of each section of the WHOQOL obtained at the start and end of CT, and analysis of variance was used to compare the difference in QOL scores for the different nutritional status categories. The Spearman’s correlation coefficient was used to evaluate the correlations between the continuous variables with normal distributions. The χ² test was used to test the association between symptoms and nutritional status. The predictive power of the sample was calculated retrospectively once the mean and standard deviations of the variables of interest had been established. The level of significance for all tests was set at 5%.

This study was approved by the Research Ethics Committee of the Federal University of Pelotas School of Medicine. The patients signed the free and informed consent form on the first day of CT.
RESULTS

One hundred forty-three patients participated in this study. Their mean age was $M=56.6$ SD=12.8 years. Most of them were females (76.2%) and almost half were from the D/E socioeconomic levels (46.7%). According to the PG-SGA administered at baseline, 86.0% were well nourished and 14.0% were moderately or severely malnourished.

The most prevalent diagnoses were breast and gynecological cancers (58.7%) (Table 1). Most of the patients had stage II cancers (46.5%) and 77.6% (n=111) received adjuvant or neoadjuvant CT (Table 1). Seventy-four patients (51.8%) had undergone surgery before CT.

The clinical course of the patients during the study varied substantially secondary to their nutritional status. Only 4.4% of the well nourished patients died or discontinued their treatment. Among the moderately or possibly malnourished patients, 43.8% died during the treatment and 14.6% could not finish the treatment. None of the severely malnourished patients could be reevaluated at the end of the treatment since 75.0% of them had died and 25% had discontinued the treatment because of a deteriorating health status.

The initial and final PG-SGA scores were compared to determine if the nutritional risk of the patients changed over the studied period. The results showed that the scores of 41.6% (n=57) of the patients increased (i.e. greater nutritional risk), 13.9% (n=19) remained the same, and 44.5% (n=61) decreased (i.e. smaller nutritional risk).

Fifty-nine patients (41.3%) experienced CT-related side effects. Table 2 shows the incidence of symptoms according to the PG-SGA.

The present study also investigated a possible association between side effects and nutritional status. The results showed that the nutritional status of 83% of the patients who experienced side effects got worse, in contrast with 15.5% of the patients who did not experience side effects ($p<0.001$).

M: mean; SD: standard deviation; $^1$CT, chemotherapy; $^2$Paired Student’s t test, $p<0.05$ level.
Table 3 shows the mean QOL scores before and after CT. Only general health increased significantly ($p=0.01$).

Analysis of variance was performed to detect variations in the different QOL domains, according to the nutritional status categories obtained at the beginning and end of the study. The results are shown in Figures 1 and 2. Malnourished patients had lower baseline QOL scores in all domains, but only their physical scores were significantly lower than those of well-nourished individuals. At the end of the study, malnourished patients had significantly lower QOL scores in most domains, except for the social relations and environmental domains.

The present study also investigated the existence of a correlation between nutritional risk and QOL scores after treatment. A small, yet statistically significant negative correlation ($r=-0.18$) was found ($p=0.03$) for the physical domain, showing that QOL increases as nutritional risk decreases. There were no significant correlations for the other domains.

**DISCUSSION**

Many factors contribute to worsen nutritional status, which in turn is associated with a worse prognosis and has a direct but not very well documented impact on the QOL of cancer patients. Some studies have demonstrated that the scores of malnourished patients in QOL assessments were worse than those of well-nourished patients$^{10,18,19}$. This study aimed to show...
the influence of nutritional status on the QOL of a cohort of cancer patients.

Most of the participants of this study were female or older than sixty years. This is due to the types of cancer presented by the cohort: breast and cervical cancers (most common cancers in females), followed by cancers of the head and neck and gastrointestinal tract (more common in older patients).

This study found that only 14.0% of the patients had some degree of malnutrition at the time of diagnosis. This may be explained by the high prevalence of breast cancer in this sample (58.7%), a type of cancer that is usually not associated with cachexia. The study also found that all patients who were severely malnourished at baseline either died or discontinued the treatment, which explains why they did not undergo the second assessment and were excluded from this sample. CT treatment was discontinued when the patient’s health declined rapidly. This demonstrates the importance of nutritional status for the prognosis of cancer patients submitted to CT.

PG-SGA seems to be a more sensitive nutritional assessment method suitable for longitudinal studies since it enables the early detection of small changes in nutritional status over short periods\textsuperscript{20}. This was evidenced by this study, since the risk of malnutrition increased for 41.6% of the patients, that is, their final PG-SGA score was greater than their baseline score.

The early identification of CT-related side effects and their appropriate management may help to reduce their impact on the patient’s nutritional status. In this study, 41.3% of patients reported some type of side effect at the end of the studied period, with dry mouth being the most common, followed by lack of appetite, early satiety and nausea. A Spanish study of cancer patients showed that the most common complaints were loss of appetite (42.2%) and

![Figure 2](image-url). Quality of life scores by domain according to nutritional status at the end of the study. Pelotas (RS) Brazil, 2004-2005.
early satiety (21.5%)21. Since the PG-SGA enabled early detection of side effects, the institution of appropriate nutritional and pharmacological measures prevented further deterioration of nutritional status.

QOL assessment has been used as an important tool for studying the impact of disease, drawing up indicators of disease severity and course and predicting treatment efficiency22. In oncology, the patient’s general health status directly impacts QOL, which, in turn, is influenced by a broad range of nutritional factors23. Furthermore, some authors have shown that poor nutritional status is indicative of worse QOL19, 24. A recent study has shown that a weight loss in excess of 10% of the body weight is significantly associated with all the main QOL domains and with symptoms such as fatigue, nausea, pain, loss of appetite and changes in bowel habits25.

Analysis of the different QOL domains suggests that the physical domain and general health improve after CT. However, only general health scores increased significantly. Contrary to our findings, an analysis of the QOL of 40 patients with colorectal cancer showed that the physical and psychological scores after CT decreased significantly26. Boery27 also used the WHOQOL-BREF questionnaire to assess the QOL of patients with lung neoplasms before and after CT and found that psychological scores decreased significantly. According to this author, the diagnosis and stress caused by the disease are already enough to promote changes, especially psychological changes. Social relations tended to worsen after CT, but the decrease was not statistically significant.

Assessment of QOL scores against nutritional status showed that malnourished patients had lower QOL scores before and after CT, mainly in the physical and psychological domains, as well as worst overall QOL and general health scores. Gupta et al.19 also investigated the association between nutritional status and QOL in 58 patients with colorectal cancer with the QLQ-C30 questionnaire and found that well-nourished patients have a better QOL, that is, better scores in the general health and physical domains. According to these authors, malnutrition is directly associated with lower QOL. Another study with 152 gastrointestinal cancer patients found that the malnourished patients had lower QOL scores, responded more poorly to CT and had a shorter life expectancy28. On the other hand, Hammerlid et al.29 found that the QOL scores of well-nourished patients with head and neck cancers did not differ from those of malnourished patients. These results may be explained by the small sample size (48 patients) of that study.

The significant negative correlation found between the PG-SGA and physical domain scores suggests that QOL improves as the risk of malnutrition decreases. Another study found significant correlations between changes in nutritional status and QOL, suggesting that improvements in nutritional status may also lead to improvements in QOL18.

One great difficulty in determining how cancer patients respond to nutritional interventions is that the metabolic changes induced by the disease make it difficult to value weight gain or improvement in the physical condition of these patients.. However, the results of this study show that QOL assessment may constitute an alternative and more sensitive tool for assessing the benefits of such interventions. A number of studies have assessed how nutritional interventions influence QOL. One study involving 125 radiotherapy patients concluded that nutritional counseling had a positive impact on various QOL aspects in cancer patients30. Peltz et al.31 studied how dietary supplementation affected QOL and found that QOL scores increased in the supplemented group, showing that improved nutritional status had a positive influence on QOL.

It would be interesting to determine which types of tumor and CT impact QOL most. The low statistical power of the present study limited subgroup analysis. Another limitation may have been the type of questionnaire used for QOL...
assessment. A generic questionnaire validated for the Brazilian population was used because back then there were no other validated questionnaires in Portuguese, specific for cancer patients (EORTC QLQ C-30). Nevertheless, other studies have shown congruent results, regardless of the type of QOL questionnaire used, and the impact of nutritional status on cancer patients should be assessed\textsuperscript{40}.

**CONCLUSION**

Cancer patients receiving CT require multidisciplinary care, especially with regard to nutrition. Nutritional support could minimize treatment side effects and reduce the risk of malnutrition. This preventive measure would also have a positive impact on QOL. Therapeutic and nutrition guidelines based on a better understanding of the relationship between nutritional status and QOL should be included in the treatment protocol of cancer patients. Furthermore, improved QOL should be considered an important outcome for these patients after any nutritional intervention.

**COLLABORATORS**

L.R. BORGES coordinated the study. L.R. BORGES and M.C. GONZALEZ conceived the study, performed the statistical analyses and wrote the manuscript. S.I. PAIVA and D.H. SILVEIRA collected the data. M.C.F. ASSUNÇÃO helped to conceive the study and reviewed the final manuscript.
