Dear Editor,

The recent precision medicine movement has pushed research towards the identification of biomarkers that can be used for early diagnosis. We designed a pilot study that explores the correlation between blood cortisol level (BCL) with depression, depression severity and clinical comorbidities in a sample of aged Brazilian subjects. We hypothesized that BCL will significantly correlate to depression, its severity and with clinical comorbidities in our sample.

Participants were selected from an epidemiological study of older residents of the city of Sao Paulo1, which screened positive for depression (depression scale-D10-score ≥ 7)2 and a pool of outpatients who received treatment for depression. Inclusion criteria were 60 years and older, and DSM-IV-TR3 criteria for major depressive disorder based on a diagnostic interview by geriatric psychiatrists. Controls were 10 adults who were at least 60 years old without depression. Exclusion criteria included dementia, other organic mental disorder, and DSM-IV-TR-criteria-based diagnoses of any psychiatric disorder other than depression. Diagnosis and exclusion criteria were assessed with the CAMDEX interview4.

We followed 11 depressed subjects. Seven patients (63.6%) began depression after age 60 (late onset depression). Both groups had more female subjects (70% of controls and 54.5% of patients). The groups were similar in terms of marital status, mini-mental score, age and education.

In the initial appointment the subjects were assessed with: Mini Mental State Examination (MMSE)5; the CAMCOG version validated for the Brazilian population3; Montgomery-Asberg Depression Rating Scale (MADRS)5; Cumulative Illness Rating Scale (CIRS)6, Bayer Activities of Daily Living Scale (B-ADL) adapted for the Brazilian populations, and the Hamilton Rating Scale for Depression (HAM-D)9. To ensure that no subjects with incipient dementia would be included in the group we applied MMSE, CAMCOG and the B-ADL. We were unable to standardize the blood sample collection time, but all cases had it collected between 6-10 am (controls 6:29-9:42 am, mean = 8:57:55 am, mdn = 8:57 am; depressed subjects 6:19-9:52 am, mean = 9:23:44 am, mdn = 9:10 am).

It was found that BCL was significantly higher in the depressed aged subjects (p = 0.049, U = 27, Wilcoxon-Mann-Whitney test), and correlated significantly with severity of both the depressive symptoms (HAM-D: p < 0.001, U = 0; MADRS: p < 0.001, U = 0; B-ADL: p < 0.001, U = 10; Wilcoxon-Mann-Whitney test) and the clinical comorbidities (CIRS-severity: p = 0.032, U = 25). Finally, depression could be predicted by BCL in a regression model (Table 1).

These findings should be taken with caution, as we did not standardize the collection time for BCL. Nevertheless, they suggest that hypercortisolemic depressed elders comprise a subgroup within depressed subjects. Their clinical course may progress with more morbidity/comorbidities and functional deficits, as shown by the statistically significant relation to all four scales applied. Elevated BCL predicts depression (p = 0.037, df = 1, B = 0.34, SE = 0.16, Table 1), which suggests that BCL might be involved in the development of depression in aged patients. The odds of 1.402 means that for each raise of 1 unit (µg/dl) of cortisol level there is 40% increase in risk of depression (95% C.I. 1.020 - 1.926).

Table 1. Logistic regression results for the prediction of diagnostic status from the BCL.
