FEDERAÇÃO LATINO-AMERICANA DE PARASITÓLOGOS (FLAP)

SEGUNDO CONGRESSO LATINO-AMERICANO DE PARASITOLOGIA
17 a 19 de setembro, 1970
CIDADE DO MÉXICO

A Federação Latino-americana de Parasitólogos teve seu primeiro Congresso em Santiago do Chile em 1967 sob a Presidência do Dr. Amador Neghme. Os novos diretores da Federação foram nomeados nesta oportunidade:

Presidente: Dr. Francisco Biagi, México
Vice-Presidentes: Dr. David Botero, Colômbia
Dr. Hugo Lumbreras, Peru
Secretário-Tesoureiro: Dr. Jorge Tay, México.

Devido ao fato do Dr. Biagi estar no momento atual trabalhando na Organização Mundial de Saúde, Unidade de Enfermidades Parasitárias em Genebra, o Dr. David Botero, da Faculdade de Medicina, Universidade de Antioquia, Medellin, Colômbia, assumiu a presidência.

Toda a correspondência e os resumos dos trabalhos devem ser dirigidos a:

Dr. Jorge Tay
Universidade Nacional de Mexico
Escuela de Medicina
Apartado: 20372
Mexico 20, MEXICO.

III CONFERÊNCIA INTERNACIONAL DE TETANO — SÃO PAULO, 1970

Será realizada em São Paulo, no período de 17 a 22 de agosto de 1970, a III Conferência Internacional de Tétano, sob os auspícios da Organização Mundial de Saúde, Oficina Sanitária Pan-americana e Academia de Medicina de São Paulo. A III Conferência Internacional de Tétano terá como local de reuniões as magníficas instalações dos Laboratórios Carlo Erba de São Paulo, que conta com perfeitas instalações audio-visuals, serviço de gravação e tradução simultânea, além de perfeito serviço de ar condicionado.

Deverão comparecer, além das delegações oficiais da Organização Mundial de Saúde e Oficina Sanitária Pan-americana, já designadas, renomados cientistas de cerca de 15 países. As sessões serão distribuídas pelos seguintes temas: Microbiologia (Prof. Nishida, do Japão), Epidemiologia (Dr. Cvjetanovic, OMS), Imunologia (Prof. Edsall, Estados Unidos), Profilaxia (Prof. Eckmann, Suíça), Terapêutica (Prof. Patel, Índia) e Estandarizações (Dra. Pitmann, Estados Unidos).

As sessões constarão de conferências sobre os respectivos assuntos, mesas redondas, temas livres e discussões abertas.

A Conferência tem como Presidente de honra o Senhor Governador do Estado e terá interessante programa de atividades sociais programadas pela Secretaria de Turismo do Estado e Prefeitura de São Paulo.

O Presidente da II Conferência Internacional de Tétano é o Prof. Ricardo Veronesi — Caixa Postal, 8091, São Paulo.
BEHAVIOUR OF A PERU STRAIN OF TRYPANOSOMA CRUZI IN Rhesus Monkeys

P.D. Marsden; A. Voller; S. K. K. Seah; C. Hawkey and D. Green

The course of infection with a Peru strain of T. cruzi was studied in 3 rhesus monkeys. An unsuccessful attempt to vaccinate one monkey is described. The trypanosomal rise during the course of infection in all 3 animals. A lymphocytosis and mild anaemia was noted in these acute infections. Orbital oedema occurred in all 3 animals following subcutaneous inoculation of the infection dose into the eyelid.

It was in the blood of the primate Callithrix penicillata that the first mammalian blood forms of Trypanosoma cruzi were seen (Chagas, 1). Since that time monkeys have been experimentally infected for a variety of reasons. Wood (18) infected a rhesus monkey with a Californian strain of T. cruzi. Both Romana (17) using South American strains and Davis (2) with a North American strain have produced orbital oedema in monkeys by conjunctival application of bug flagellates. Torres and Tavares (16), successfully infected Cebus monkeys with three strains of T. cruzi isolated from acute cases of Chagas' disease. They point out that monkeys are particularly suitable for experiments of long duration since they survive the acute phase of the disease. Unexplained T. cruzi infections of Rhesus monkeys in laboratories have been noted (Fulton and Harrison, 5). Examining this problem Hoare feels that such infections in Indian monkeys could have been acquired in the various animal houses possibly by bed bug transmission. In wild monkeys in South America T. cruzi infections are widely prevalent (Dunn et al., 4; Marrinelle, 9).

One of our interests in studying this infection in primates has been to evaluate vaccine therapy. Muniz et al. (13) were unsuccessful in demonstrating a protective action of a vaccine of merthiolate treated T. cruzi cultural forms in rhesus monkeys. We report here on two initial experiments using a Peru strain of Trypanosoma cruzi to infect rhesus monkeys.

MATERIAL AND METHODS

Infection was induced by inoculation of a known number of trypanosomes from mouse blood into the upper eyelid. This site was chosen because the anticipated subsequent oedema would give some indication of the progress of the infection. Parasitaemia was expressed as number of trypanosomes per 100 fields of a monolayer film of fresh blood, examined at a magnification of 500 times. Haematological observations done by standard techniques included haemoglobin, packed cell volume, red cell count, white cell count and differential, platelets, reticulocytes and blood sedimentation rate. The indirect fluorescent antibody test was the serological test employed in both experi-

Department of Clinical Tropical Medicine, London School of Hygiene and Tropical Medicine and the Nuffield Institute of Comparative Medicine.
Accepted for publication on 6 January, 1970.
ments and the complement fixation test was also done in the second experiment.

All 3 monkeys had their IgG and IgM levels estimated by the radial diffusion technique of Mancini et al. (8) using Hyland Immunoplates.

These are expressed as percentage of the normal in the first experiment and as mg/100ml, in the second experiment. When the monkeys were killed tissues were fixed in 10% formal saline sectioned and stained with haematoxylin and eosin (By Dr. D. S. Ridley). In the first experiment conjunctival discharge, saliva and urine were examined for trypanosomes.

RESULTS

Experiment 1.

A male year old rhesus monkey (4.6 kilos) was infected with the Peru strain of Trypanosoma cruzi originally isolated in Peru in 1963 (Nussenweig and Goble 14). The immediate previous history of the isolate was that it had been brought from America in Rhodnius prolixus and had been passaged 5 times in CFI mice prior to this experiment. 4 million trypanosomes from mouse blood in one millilitre of heparinised serum saline suspension were injected into the right upper eyelid. Though initially there was no reaction, by the sixth day both lids of the right eye were red, oedematous and swollen. At this time trypanosomes were present in the conjunctival discharge. On the 17th day at the height of parasitaemia no trypanosomes could be detected in the saliva or urine of the monkey either by direct examination, centrifugation or culture.

Figure 1A shows the course of parasitaemia in relation to changes in the serum IgG, IgM and fluorescent antibody levels. The IgM level rose to a maximum on the 11th day and remained elevated. The IgG rose slightly at the end of the experiment. The fluorescent antibody level was slow to rise, but was still developing when the animal was killed on the 34th day.

Table 1 shows the haematological data gathered on this monkey.

The slow progressive fall in haemoglobin might conceivably be related to venepuncture although only 5 ml of blood were withdrawn. The white cell count rose at the end of the experiment and there was a very significant increase in the proportion of lymphocytes. There was no eosinophilia. When the animal was killed on the 34th day the right eyelids were still red and slightly swollen. A chronic inflammatory exudate and leishmanial nests were present in these eyelids but the left eyelids were normal. Many nests of leishmania were found in the right parotid gland indicating the route of dissemination. Scanty leishmania were found in the auricles of the heart and the smooth muscle of the intestine. There was lymphocytic infiltration of all these organs and of the skeletal muscle. The liver showed fatty degeneration. No leishmania were found in brain biopsies, parotid gland, spleen, lung, testis or bladder. At the time of death the parasitaemia was subpatent and this animal would probably have gone on to develop a chronic infection.

Experiment 2.

Our experiment was partly invalidated because monkey Number 25 which we attempted to vaccinate developed tuberculosis of the lungs which was confirmed as post mortem. Dr Henry Seneca of Columbia University, New York, kindly supplied us with some freeze dried extract of cultural T. cruzi of the Tulahuen strain prepared as described in this paper (Seneca and Peer, 15). We gave the monkey 3 inoculation without adjuvant prior to infection at 33 days (26 mg intraperitoneally), at 30 days (40 mg intraperitoneally) and at 13 days (40 mg subcutaneously). No adjuvant was used and a slight rise in IgG level was noted during this schedule and the complement fixation test became positive in low titre. Monkey Number 26 was given no vaccination and used as control saline only being infected.

Since both these male rhesus monkeys were half the weight of our previous monkey (2.3 kilos) we gave them half the dose of trypanosomes (2 million) isolated from mouse blood after 77 previous passages in CFI mice by inoculation into the left upper eyelid. By 6 days
both monkeys had orbital oedema of the left eye. The non-vaccinated monkey is illustrated at 9 days (Figure 1) and 20 days (Figure 2). Trypanosomes were found in the conjunctival discharge from both animals. As can be seen in the second photograph the lesions went on to ulcerate. The course of parasitaemia, haemoglobin, IgG and IgM levels and serological antibody titres are given in Table 2. The haemoglobin and PCV again fell although in the case of the tuberculous monkey (N.° 25) it is of little significance. While IgG levels remained static, again in both monkeys IgM levels rose. Both fluorescent antibody titres and complement fixing antibody titre showed a progressive rise with the passage of time. Our vaccination schedule did not appear to influence the course of the disease. Both animals were killed on the 29th day. The left eyelids of both monkeys showed leishmanial nests and a chronic inflammatory cell infiltrate of mainly lymphocytes. Similar lymphocytic infiltration was present in the auricular muscle and skeletal muscle but no leishmania were seen.

**DISCUSSION**

The Peru strain of *Trypanosoma cruzi* induces a non-fatal acute infection in rhesus monkeys since a decline in parasitaemia is noted even in these short term experiments. The relatively mild tissue reactions and absence of leishmania other than at the site of inoculation is in keeping with this observation. A similar persistent multiplication at the site of inoculation has been noted in Beagle dogs (Marsden and Hagstrom, 10). Orbital oedema developed in all 3 monkeys with this strain and was useful in assessing the progress of the infection. Such a reaction was rare in Beagle dogs inoculated in a similar manner.

The marked lymphocytosis noted in the first experiment is a feature of human acute infections (Dias, 3). A fall in haemoglobin and PCV was noted in all 3

monkeys during the course of the infection but this may be associated with venepuncture. If there is a true anaemia, from our data it appears to be normocytic normochromic anaemia. The reticulocyte count does not suggest active haemolysis.

Both the fluorescent antibody test and the complement fixation test showed rising titres with the course of the infection. It is noteworthy that a positive CFT was observed in the vaccinated animal before challenge with living organisms. Vaccination was not successful but the type of schedule can be modified and we were using an extract derived from a different strain. Current experiments are in progress and designed to explore the use of adjuvants with a vaccine of freeze dried cultural forms of this Peru strain and make similar immunological observations on long term infections in rhesus monkeys. Perhaps the most interesting finding was the constant observation of a progressive rise in the IgM level while the IgG level showed little change. Similar elevation of the IgM levels has been noted in Trypanosoma brucei infections of
monkeys (Mattern et al., 11), and is such a marked feature of human infections as to be of diagnostic value (Mattern et al., 12). It is important to ascertain whether a similar phenomenon occurs in human T. cruzi infections.
