**Abstract**

**Introduction:** Chagas disease (CD) affects 5.7-7.0 million individuals worldwide, and its prevalence reached 25.1% in the state of Bahia, Brazil. There is an association between the prevalence of CD, the socioeconomic status of the population, and the risk of re-emergence due to non-vectorial transmission, such as blood transfusion. This study determined the seroprevalence of *T. cruzi* infection among blood donors in the state of Bahia, located in northeastern Brazil, and their epidemiological profile during a 10-year period. **Methods:** We performed a descriptive cross-sectional study involving a database review. Data were collected from patients with non-negative results for *T. cruzi* infection during a 10-year period. **Results:** A total of 3,084 (0.62%) samples were non-negative for *T. cruzi* infection in an initial serological screening, and 810 (0.16%) samples were non-negative in the second screening. The correlation between infection and age (30 years or older) and between infection and lower educational level (12 years or less) in the first and second screening was statistically significant. The seroprevalence of *T. cruzi* infection was higher in men in the first screening. In addition, 99.52% of the municipalities of Bahia had at least one case of CD. Livramento de Nossa Senhora and Salvador presented the highest disease prevalence and recurrence, respectively. **Conclusions:** The seroprevalence of *T. cruzi* infection in these populations was lower than that found in other studies in Brazil but was comparatively higher in densely-populated areas. The demographic characteristics of our population agreed with previous studies. 

**Keywords:** Chagas disease. Blood donor. Seroepidemiological studies.
Vectorial transmission is more common in endemic areas, in which the parasite is transmitted by contact with feces or urine of infected blood-sucking triatomine bugs (Hemiptera, Reduviidae). Other transmission routes include the consumption of contaminated foods or beverages, tissue and organ transplantation, mother-to-child transmission during pregnancy, laboratory accidents, induced or criminal infection, and blood transfusion. The transmission of *T. cruzi* via blood transfusion has increased because of urbanization and modernization of medicine and is the predominant route of transmission in both endemic and non-endemic areas, especially in countries in which screening tests for CD are not mandatory in blood banks. Furthermore, *T. cruzi* tolerates extreme conditions, such as low temperatures (–80 to 4°C), and freezing and thawing, indicating that the parasite can be transmitted in all blood components, including granulocytes, red blood cells, and plasma.

*T. cruzi* infection occurs predominantly in individuals living in rural areas. However, the epidemiological status of CD has changed as a consequence of migration flows from rural areas to the periphery of large cities, where the presence of forest remnants increases the risk of disease transmission.

Human CD is classified as a neglected transmitted disease, primarily affecting communities with higher social vulnerability, characterized by low income, poor housing and hygiene conditions, and low levels of schooling. For this reason, among parasitic diseases, CD is the most strongly associated with population vulnerability, in which the majority of seropositive individuals have these risk factors.

Studies on CD should assess ecological, biological, social, and economic parameters to identify risk factors associated with disease development and progression. Furthermore, these studies reduce the risk of infection by producing knowledge for scientific and technological innovations.

Technologies capable of reducing the risk of transmitting infectious diseases through transfusion are critical to prevent the spread of contagious agents and ensure the quality of blood for transfusion. Studies of discarded serological tests are capable of creating relevant technologies to improve the quality of blood transfusion. Serological screening has been used in several countries to improve public health programs. However, this type of testing is facing ethical, operational, and financial difficulties.

Training the teams responsible for collecting pre-donation information is critical, given that adequately collected epidemiological data may help avoid transmission and decrease costs in the public health system.

In addition to avoiding transmission, identifying individuals with suspected disease allows researchers to identify regions with a higher risk of transmission and the most relevant epidemiological characteristics associated with seropositivity. Moreover, identifying places of birth and residence with higher prevalence may help characterize areas with a higher risk of transmission in the state of Bahia.

Previous studies with blood donors reported that the percentage of non-negative results was higher among married individuals, people in stable relationships, and subjects with lower education levels. The percentage of infection was higher in men, although one study found that the rate was higher in women. The number of cases was higher in older age groups, especially in individuals older than 30 years, and the percentage of infection between men and women differed according to age group.

The objective of this study was to determine the seroprevalence of *T. cruzi* infection and describe the epidemiological profile of blood donors from the Hematology and Hemotherapy Foundation of Bahia (HEMOBA) with non-negative results for *T. cruzi* infection detected by screening tests performed during a 10-year period (February 2008 to February 2018) in the state of Bahia. The specific objectives were to determine the most relevant epidemiological characteristics of blood donors with non-negative results for CD and identify the municipalities of origin of this population.

**METHODS**

**Study design:** Descriptive cross-sectional study involving a database review.

**Target population:** All blood donors from HEMOBA in the state of Bahia, Brazil, examined during the study period. HEMOBA is the official blood service in Bahia, and its units cover all health macro-regions in the state.

**Diagnostic criteria:** Non-negative results for *T. cruzi* infection;

**Selection criteria:**

- **Inclusion:** Donors with non-negative results for *T. cruzi* infection detected in serological screening tests performed at HEMOBA;
- **Exclusion:** Donors with negative serology in the second screening;

**Variables:** Gender, age, place of residence, place of birth, education level, racial group, marital status, number of annual blood donations, and test results in the first and second screening;

**Clinical selection of candidates and release of blood bags:** To minimize the risk of *T. cruzi* infection via blood transmission, the Brazilian Ministry of Health has issued several ordinances, the most recent being Ordinance 5, which was published in the Official Gazette of the Union on September 28, 2017 and lists the criteria for the clinical selection of candidates for blood donation. HEMOBA created a standard computerized questionnaire (Hemovida System) following these criteria and disclosed the data for the study. The methodology used for the release of blood bags followed the recommendation of the Ministry of Health according to Ordinance 5.

**Serological screening:** High sensitivity tests are mandatory. Between January 1991 and January 2015, screening tests for CD among blood donors at HEMOBA used anti-*T. cruzi* antibodies and ELISA from MUREX (FRA) and BIOMÉRIEUX (FRA). Since February 2015, HEMOBA adopted serological screening by chemiluminescence using IgG and IgM class antibodies. These antibodies were purchased from ABBOTT (IL, USA).
until February 25, 2016, and from DIASORIN (ITA) since then to date. HEMOBA uses the same serological test in donors in the second screening and sends them to a referral unit in case of positivity.

**Statistical analysis:** Descriptive analyses were performed using the statistical package Epi Info 2000 (CDC, Atlanta, GE, USA). The X² test was used to compare proportions, and a level of significance of 5% (p<0.05) and a confidence interval of 95% were adopted in all tests. Qualitative variables were expressed as absolute numbers and relative frequency.

**Georeferencing:** The information was georeferenced using the software Qgis version 2.0 to identify groups with high rates of non-negative results for *T. cruzi* infection according to the place of residence. The natural breaks method with five class intervals was used because the variables were discrete.

**Ethics**

The adopted procedures were in accordance with the ethical standards of the Research Ethics Committee of the Gonçalo Moniz Institute (Fiocruz, Bahia, Brazil) and with the Helsinki Declaration of 1964, revised in 1975, 1983, 1989, 1996, and 2000. The consent form was waived because the analysis was based on a database. However, no personal identification data were used to ensure the complete anonymity of blood donors. The research did not cause any physical, psychic, moral, intellectual, social, cultural, or religious risk to blood donors.

**RESULTS**

During the 10-year study period (February 22, 2008 to February 21, 2018), 494,010 donors and 816,346 blood samples were examined at HEMOBA. In a preliminary analysis, 3,084 (0.62%) non-negative samples were identified. All samples reactive for *T. cruzi* are considered non-negative by HEMOBA. Patients whose test results were non-negative or inconclusive were advised to return to HEMOBA to undergo a second screening. In the first screening, the prevalence of non-negative results for *T. cruzi* infection was 0.62% (3048 samples). The prevalence was higher in blood donors aged 30 years or older (PR, 1.3236; 95% CI, 1.2040–1.4550) when compared with those with at least 12 years of education. There was no statistically significant association between the place of birth and residence and the prevalence of non-negative serology in this population (Table 1).

The analysis of data from the second screening indicated that the prevalence of non-negative results for *T. cruzi* infection was 0.15% (810 samples). The prevalence was higher in blood donors aged 30 years or older (PR, 3.4497; 95% CI, 2.8547–4.1689) and donors with 12 years of schooling or less (PR, 2.6943; 95% CI, 2.1154–3.4317). There was no statistically significant association between non-negative serology, gender, and the place of birth and residence in Bahia (Table 1).

The data on the prevalence of non-negative results according to the marital status and racial group are shown in Table 2. Given the high miscegenation of the population in Bahia, it is difficult to classify the study sample into racial groups. Notwithstanding, there was no association between prevalence rates and racial groups.

The data on the place of residence of blood donors with non-negative results for *T. cruzi* infection were georeferenced and summarized in cartographic representations. The prevalence rates during the 10-year period in the first and second screening performed at HEMOBA is shown in Figure 1.

During the study period, 415 municipalities of Bahia were identified as places of residence of blood donors who presented at HEMOBA. Only the municipalities of Almadina and Jiquiriçá were not represented in the samples in this period. In addition, 608 cities outside of Bahia were identified as places of residence, with 11,656 donors (1.43%); however, these donors were not included in the geographical representations because these cities were outside the cartographic limit of the state.

According to the data from the first screening, the municipalities with the highest prevalence were Livramento de Nossa Senhora, located in the center-south of the state (n=2, 100%), Cotegipe (n=14, 6.31%), Wanderley (n=17, 6.69%), Sebastião Laranjeiras (n=5, 7.25%), Mulungu do Morro (n=8, 7.92%), Jaborandi (n=4, 8.33%), and Lajedinho (n=1, 10%). In the second screening, the municipalities with the highest prevalence were Livramento de Nossa Senhora (n=2, 100%), Boa Vista do Tupim (n=1, 3.85%), Wanderley (n=11, 4.33%), Botuporã (n=1, 4.7%), and Lajedinho (n=1, 10%).

The places of residence with at least one non-negative result per year between February 2008 and February 2018 in the second screening are shown in Figure 2.

The municipalities with the highest number of recurrences was Salvador (state capital) (11 out of 11 years), Feira de Santana (located in the north-central region of the state) (9 out of 11 years), Barreiras (8 out of 11 years), and Santo Antônio de Jesus (8 out of 11 years).

**DISCUSSION**

Human CD is endemic in Brazil, despite the success of government initiatives adopted in the past few decades.

*% of total blood donors that belong to this category between 2008 and 2018.
Measures for eradicating vectorial transmission are constantly debated. However, much remains to be done because the disease is transmitted by other routes, including blood transfusion, which has gained importance in the epidemiological literature. Studies investigating the prevalence of CD in blood donors can provide quantitative epidemiological data and guide interventions in high-risk areas and population groups.

Among a population of 494,010 donors and 816,346 blood donations during the 10-year period, 3,084 (0.62%) samples were non-negative in the first screening. Among 1,486 donors, 810 (0.16%) samples were non-negative in the second screening. These rates may be underestimated because, despite strong guidance on the importance of second screening, many donors did not return to the blood units and therefore were not included in the analysis.
The prevalence rates were lower than those found in other studies conducted in Brazil but were relatively higher in densely-populated regions. Dias et al. (2000) found that the seropositivity for *T. cruzi* infection between 1987 and 1994 ranged from 0.77% to 2.22% in Bahia and from 0.69% to 0.88% in the northeast region of Brazil. Dias (1998) reported that the seropositivity between 1988 and 1990 in Brazil was 0.97% and decreased in the following years: 0.7–1.1% in 1991, 0.7% in 1993, and 0.75% in 1994; the seropositivity in the northeast of Brazil was 0.36% in 1994. In contrast, Monich (2016) found that the discard rate of donated blood in Curitiba between 2003 and 2012 varied from 0.6% to 0.9%, whereas Slavov et al. (2016) indicated that the discard rate in the state of São Paulo between 2012 and 2014 was 0.1%. It is worth mentioning that the methodology used in some studies did not involve second screening, and prevalence was calculated using donors with positive serology in the first screening. The prevalence in the present study using this approach was 0.62% (3,084 individuals).

The seroprevalence of *T. cruzi* infection was higher in individuals aged 30 years or older and individuals with 12 years or less of education in the first and second screening, and seroprevalence was significantly higher in men in the first screening. These results agree with previous studies. Data on seroprevalence rates according to marital status and racial group are summarized in Table 1.

With respect to the geographical distribution of the places of residence, 99.52% (415) of the municipalities of the state of Bahia and 608 municipalities outside the state borders had at least one diagnosed case of CD during the 10-years study period. Georeferencing was performed according to the place of residence rather than the place of birth because maternities are unavailable in many cities in the interior of the state. Moreover, the place of residence is a more reliable parameter because it represents, in most cases, the place where individuals are most exposed to infection throughout life.

Georeferencing enabled the identification of municipalities with higher seroprevalence (Figure 1). Increased access to blood transfusion services is a contributing factor for higher recurrence. Salvador, the state capital, is home to the HEMOBA headquarters and has the highest number of blood donors and donations, which may explain the higher rate of recurrence in this city. In addition, HEMOBA’s blood collection stations were being implemented in municipalities of the state throughout the study period, which might have increased the number of blood donations.

Seroprevalence analysis of CD can accurately assess the risk of transfusion-related CD and the rate of disease transmission. This study identified high-prevalence regions in Bahia, allowing performing serological and epidemiological surveys in these areas and collecting epidemiological data to formulate health policies.
