

Translation and cultural validation of the Revised Illness Perception Questionnaire for Healthcare Professionals for Brazilian Portuguese

Tradução e validação cultural do Questionário de Percepção de Doença Revisado para Profissionais de Saúde em português brasileiro

Fernando DE NIGRIS VASCONCELLOS¹, Felipe GREGÓRIO LIMA¹, Enedina Maria Lobato de OLIVEIRA¹

ABSTRACT

Background: Multiple sclerosis progression and disability can be rated differently by healthcare professionals. Therefore, how physicians perceive the disease can impact treatment decisions. There are no previous studies on this matter. **Objective:** To translate and transculturally validate the Revised Illness Perception Questionnaire for Healthcare Professionals (IPQ-R HP), for use in Brazilian Portuguese. **Methods:** The process used to validate the IPQ-R HP was based on the steps presented in the guide proposed by Dorcas Beaton. The final version of the IPQ-R HP had 38 questions, divided into seven different dimensions to assess the patient's disease. Also, two clinical cases that were representative of real-life patients with multiple sclerosis (MS) were assembled to consider the two main profiles of the disease. We applied the questionnaire to neurologists at the Federal University of São Paulo (UNIFESP) to assess their perception of MS. These doctors also answered a brief survey to establish the profile of the interviewees. For statistical analysis, we used Bayesian CFA models and kappa statistics. **Conclusions:** The kappa statistics showed a general agreement of 0.4. For the Bayesian CFAs with seven-factor correlation solution, we had a poor fit for case 1 with a 95% confidence interval ranging from -52.893 to 273.797 and a PPP of 0.107. Regarding case 2, the model did not converge even after 50,000 iterations, which indicated that the specified model (i.e. seven-factor correlation solution) for case 2 was inadmissible. Thus, the IPQ-R HP questionnaire in Brazilian Portuguese has not been validated.

RESUMO

Antecedentes: A progressão da esclerose múltipla e a incapacidade podem ser avaliadas de formas diferentes por médicos. Portanto, a forma como estes percebem a doença pode afetar as decisões de tratamento. Não há estudos anteriores sobre o assunto. Procuramos traduzir e validar o Revised Illness Perception Questionnaire-Revised Healthcare Professionals (IPQ-R HP). **Objetivos:** Validação transcultural da versão IPQ-R HP para português. **Métodos:** O processo de validação do IPQ-R HP foi baseado nas etapas apresentadas no guia proposto por Dorcas Beaton. A versão final do IPQ-R HP continha 38 questões, divididas em sete dimensões diferentes para avaliar a doença do paciente. Além disso, dois casos clínicos representativos de esclerose múltipla (EM) foram criados para contemplar os dois perfis principais da doença. Aplicamos o questionário a neurologistas da UNIFESP para avaliar sua percepção sobre a EM, além de uma pesquisa para estabelecer o perfil dos entrevistados. Para a análise estatística, usamos modelos CFA Bayesianos e estatísticas kappa. **Conclusões:** A estatística kappa mostrou concordância geral de 0,4. Para os CFAs bayesianos com solução de sete fatores correlacionados, tivemos um ajuste ruim para o caso 1 com um intervalo de confiança de 95% variando de -52,893 a 273,797 e o PPP de 0,107. Em relação ao Caso 2, o modelo não convergiu mesmo após 50000 iterações, indicando que o modelo especificado (ou seja, solução de sete fatores correlacionados) para o caso 2 é inadmissível. Assim, o questionário IPQ-R HP em português não é validado.

INTRODUCTION

Multiple sclerosis (MS) is a demyelinating, progressive, degenerative autoimmune disease of the central nervous system (CNS), with prevalence ranging from about 15 to 20/100,000 inhabitants, in Brazil¹. The progressive nature of the disease, which gradually limits the patient's functionality, makes early treatment with effective drugs necessary². Early and adequate treatment allows a better prognosis for the patient and better use of the resources destined for the disease³.

Diseases that can present in various ways with diverse symptoms can possibly be interpreted differently by each professional during patient care. For example, Arat et al. demonstrated that doctors who treat patients with systemic lupus erythematosus (SLE) have quite different perceptions of the disease^{4,5}. Those authors developed the Illness Perception Questionnaire-Revised for Healthcare Professionals (IPQ-R HP) to highlight differences in perception of SLE. Thus, they were able to describe how specialists have different views on the consequences, limitations and clinical evolution of the disease and on the ways in which their understandings could affect this disease^{5,6}.

Given the clinical characteristics of MS, its symptoms, clinical progression and accumulation of disability over time, an understanding of how neurologists perceive MS can be an important tool for improving therapeutic decisions⁷. Moreover, the peculiarities of the Brazilian National Health System (Sistema Único de Saúde, SUS) and its high-cost drug program make Brazil an unusual country in terms of public health. Every patient in Brazil who is diagnosed with MS receives disease-modifying treatment free of charge. This is a high-cost treatment with a major impact on public spending within government health-care policies. Therefore, there is a need for accurate treatment, and this makes the physician's perception of the disease a fundamental issue.

To start filling the knowledge gap on how a physician's perception of illness and his/her expertise may interfere with patient care, and to gather information on how multiple sclerosis is perceived by neurologists, we aimed to translate and validate the IPQ-R HP questionnaire for use in Brazilian Portuguese.

Objectives

To translate and culturally validate the Revised Illness Perception Questionnaire for Healthcare Professionals (IPQ-R HP).

METHODS

Validation of the questionnaire

The IPQ-R HP questionnaire developed by Arat et al. consists of 38 questions in a Likert-scale format, through which participants explain their level of agreement with the topics addressed in terms of five possibilities, ranging from "totally

disagree" to "totally agree". The questions are distributed in seven different dimensions of the disease, also called domains of the questionnaire: 1) the consequences of the disease for the patient; 2) the perception of time concerning the duration of the disease, whether it has a prognosis of rapid improvement or not; 3) the patient's ability to control his/her illness; 4) the effectiveness of some type of treatment that is carried out in the context of controlling the disease; 5) the individual's understanding of his/her illness; 6) the perception of a possible cyclical nature for the disease, when analyzed over a longer period; and 7) the emotional experience that the patient has regarding his/her illness⁶.

The validation process was based on the guide proposed by Beaton et al.⁸. The first step was the translation in Portuguese. The first translation was made by a neurologist who was a specialist in demyelinating diseases. The second translator was made by a sworn translator without knowledge of medicine. The third translation was made by author responsible for this study.

The second step was to produce a synthesis of all the translations, in which the aim was to eliminate discrepancies between the versions and create a unified text.

The third step was to produce a "back-translation", i.e. a translation of the unified version of the text in Portuguese, back to the language in which the questionnaire had been created. This process was necessary in order to evaluate how reliable the text obtained through merging the translations was, in comparison with the original. For this, the translation was done by the same sworn translator.

The fourth stage encompassed all the translators, healthcare professionals, and professionals working with linguistics. The function of this committee was to analyze the differences and to prepare a version of the questionnaire that was considered pre-final. In comparing the two versions, it could be seen that among the 38 items, only two of them presented more significant differences, while most were the same as the original, and a few items differed only in word order. We submitted the documents that reported on the validation process, together with the translated questionnaire, to the original developers of the questionnaire so that they could verify the steps were followed and approve the final content of the translated version.

In addition to the questionnaire, two clinical cases of multiple sclerosis were developed based on real clinical cases of relapsing-remitting and primary progressive MS. These were given to the participants together with the questionnaire. They were created to represent patients under follow-up at the Neuroimmunology Clinic of the Department of Neurology and Neurosurgery, Escola Paulista de Medicina, Federal University of São Paulo (UNIFESP). Thus, each study participant completed the IPQ-R HP twice, i.e. for each clinical case.

All stages of this project, which all involved doctors whose participation was voluntary, were approved by the Research Ethics Committee of UNIFESP, under the number CAAE 86002717.1.0000.5505.

Population

The final Brazilian Portuguese version was applied between April 2018 and November 2019 (Table 1). Prospectively and consecutively, neurologists were asked to answer a questionnaire based on the clinical cases presented to them, after signing a consent form.

Initially, we applied a physical version of the questionnaire in face-to-face interviews. However, it was observed that such

a model was not practical for the subjects to answer during the working day. Therefore, an online version of the questionnaire was developed.

The inclusion criteria were that the subjects needed to be neurologists working in the neurology discipline of the Department of Neurology and Neurosurgery, Escola Paulista de Medicina, UNIFESP; or neurology residents with at least two years of full training and a minimum of five weeks of internship

37. Ter esta doença deixa meu paciente ansioso					
38. A doença de meu paciente faz com que ele/a tenha medo					

at a demyelinating disease clinic, during their residency. The following physicians were excluded: physicians who were temporarily in an internship of less than 6 months at the institution; and pediatric neurologists without previous neurology training. Neurologists who claimed to care for more than 10 patients with MS per month were deemed to be MS specialists.

In addition, epidemiological data were collected from the study volunteers, including the following: age, sex, length of time since graduation, postgraduate qualifications, work sector and number of patients with MS treated by the physician.

Statistical analysis

We described categorical data as absolute values (n) and relative frequencies (percentage); and continuous variables in terms of mean and standard deviation. Kappa statistics⁹ were used to quantify the level of agreement among raters, considering relapsing-remitting and primary progressive MS cases separately.

A variety of criticisms of kappa statistics have emerged based on different statistical elements. Klein¹⁰ revised Gwet's framework^{11,12}, with discussion of different alternative agreement

coefficients (ACs), and this revision was implemented in Stata version 14 (StataCorp, 2009) under the command *kappaetc*¹⁰. The percentage of agreement and different variations of kappa were calculated as the following formulations: Brennan and Prediger¹³, Cohen⁹, Gwet's AC¹¹ and Krippendorff's Alpha¹⁴). For all the coefficients, unweighted analysis was conducted; therefore, the identity matrix was considered as described by Klein¹⁰, and 95% confidence intervals [CI] were calculated. According to the benchmark scale proposed by Landis & Koch¹⁵, the coefficient interpretations are as follows: below 0.00 indicates poor agreement; 0.00 to 0.20 slight; 0.21 to 0.40 fair; 0.41 to 0.60 moderate; 0.61 to 0.80 substantial; and 0.81 to 1.00 almost perfect. Kappa coefficients for both general neurologists and MS neurologists were calculated.

General model testing

We performed a confirmatory factor analysis (CFA) for evidence of factorial construct validity using the 63 respondents for two cases (1 and 2). In this, the 38 items were considered as ordered-categorical variables. A Bayesian estimator was used rather than the traditional frequentist approach. In Mplus¹⁶, the frequentist default estimator is the weighted least square using a diagonal weight matrix with standard errors and mean and variance-adjusted (WLSMV) when the indicators observed (e.g. items) are dichotomous or ordered-categorical.

According to Brown¹⁷, the Bayesian method has several potential advantages over the traditional frequentist approach. For our study, the Bayesian method may have been better for a small sample, given the number of items under evaluation. For the Bayesian CFA, we used loadings with mean at zero and variance at 0.01, as prior factors. A prior factor is a previously held belief concerning likely parameter values, before collecting related data.

To evaluate the goodness-of-fit for the Bayesian CFA models tested, the following fit indices were used: posterior predictive p-value (PPP) and associated 95% credibility interval¹⁸. While a low PPP ($p < 0.05$) and positive 95% lower limit point to a poor model fit, a well-fitting model is expected to show a PPP of around 0.5 and a symmetrical 95% credibility interval centering around zero. We used a minimum number of total iterations of 50,000, including the discards. Thus, depending on when convergence occurs, more than 25,000 iterations could be used for subsequent distribution.

RESULTS

The final Brazilian version of the IPQ-R HP can be seen in Table 1. Seventy neurologists were recruited and agreed to participate but only 63 returned the questionnaire completely answered (Figure 1).

The neurologists' profile and characteristics are described in Table 2. Briefly, the participants were predominantly male (in the proportions of 2:1) and young (average of 12 years since

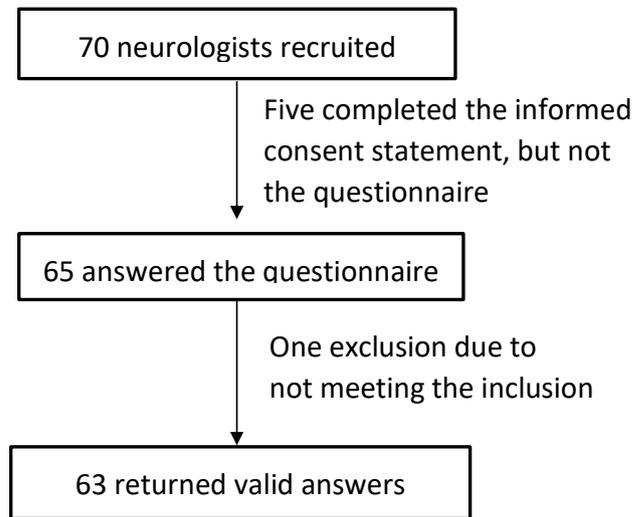

Figure 1. Diagram showing study recruitment and enrollment.

Table 2. Main demographic characteristics of 63 neurologists working at UNIFESP who returned valid answered questionnaires.

Sex	Male: 66.7% Female: 33.3%
Age	Average: 35.7 years (range: 27 to 63)
Length of time since graduation	Average: 12 years (range: 4 to 39 years)
Residency	Ongoing: 23.8% Concluded: 76.2%
Postgraduate studies (1.6% abstention rate)	Without/Ongoing: 49.2% Master's: 28.6% Doctorate: 20.6%
Work sector (6.3% abstention rate)	Private healthcare: 6.3% Public healthcare: 9.6% Both: 77.8%
Number of patients with MS treated (6.5% abstention rate)	< 10/month: 33.3% > 10/month: 22.2% < 10/year: 26.9% > 10/year: 11.1%

MS: multiple sclerosis.

graduation). Around 24% had not completed their residency and only 20.6% had finished their PhD. The vast majority were working in both the private and the public sector and only 22% of the participants were caring for more than 10 patients with multiple sclerosis per month.

The kappa statistics showed a general agreement of 0.4 for both cases 1 and 2. The kappa values for the neurologists belonging to the MS specialists' group were 0.48 and 0.5, for cases 1 and 2, respectively. For the Bayesian CFAs with seven-factor correlation solution, we had poorly fitting models as

follows: case 1 showed a 95% confidence interval for the difference between the observed and the replicated chi-square values ranging from -52.893 to 273.797, with a PPP of 0.107. In the case of Case 2, the model did not converge even after 50,000 iterations, thus indicating that the model specified (i.e. seven-factor correlation solution) for case 2 was inadmissible.

DISCUSSION

The perception of illness can be defined as the way in which an individual perceives and mentally plans to live with an illness¹⁹. Beliefs and attitudes are predictors of treatment adherence in relation to different chronic diseases, such as SLE, asthma and Crohn's disease¹⁹. However, assessing the effect of the healthcare professional's conceptualizations on treatment and clinical evolution is an arduous task. For example, neurologists and psychiatrists have different views on epilepsy and this can lead to discrepancies that affect the treatment of patients who are followed up by both specialists²⁰.

In multiple sclerosis, the perception of disease is associated with and influences the interpretation of symptoms and treatment effects^{21,22}. In our study, we aimed to translate the disease perception questionnaire for healthcare professionals (IPQ-R HP) into Brazilian Portuguese and validate it⁶. Furthermore, we tried to assess the perceptions that neurologists working in tertiary teaching hospital would have of a complex neurological disease, such as multiple sclerosis.

Overall, we observed a kappa of 0.4, i.e. a percentage agreement of 40%. The level of agreement was slightly higher among specialists, ranging from 48 to 50%, than among non-specialists. This suggesting that the level of agreement was acceptable but not enough to consider the questionnaire validated. Thus, we need to consider that the sample size and the complexity of the questionnaire were limiting factors.

On the other hand, the characteristics of our population may have been one explanation for our results. It was a young population, with an average of 12 years of neurology practice and little MS training. The small difference observed between general neurologists and specialists in multiple sclerosis suggests that the study population could have included a larger number of neurologists with experience in the care of patients with MS, which thus might have enabled validation of the questionnaire. However, our result reinforces the idea that motivated this study in the first place: neurologists have different

perceptions about multiple sclerosis, and this may affect the treatment and care provided for patients.

In terms of CFA, our sample size was small, even though we used a Bayesian approach. The five categories of responses and the large number of items (38) in relation to such a small sample size generated difficulties in estimating item thresholds and factor loadings. This explains the non-convergence for case 2. Differently from case 2, case 1 returned poor fit indices, meaning that the model at least converged.

Some ideas for the future specification of the questionnaire might include reducing the number of items, especially the items with similar wording within the same domain of evaluation. Moreover, the number of response categories per item could be reduced from 5 to 3, in addition to reducing the number of items. This would consequently reduce the complexity of the questionnaire and generate a more parsimonious model.

It was seen that some items did not show the presence of the full range of response categories (for example, items 6 and 8, in case 2). This indicates that the neurologists chose not to use the full spectrum of response options that were available to them. Generally, the most common response categories were at the endpoints (1 or 5). Thus, intermediate responses were not being endorsed and, consequently, were not informative about the factors under investigation.

Moreover, the original questionnaire was developed to assess SLE and it is possible that some of its domains were inappropriate for capturing some matters of relevance for rating with regard to multiple sclerosis⁵.

Our results are modest but point to an interesting path. The illness perception questionnaire needs to be improved, and a better, shorter version should be tested in the future in order to investigate whether the slight difference observed among neurologists will prevail.

In conclusion, the IPQ-R HP questionnaire (Revised Illness Perception Questionnaire for Healthcare Professionals) in its Brazilian Portuguese version showed acceptable agreement, but not adequate for its validation.

ACKNOWLEDGMENT

The authors would like to thank the University of Leuven, Belgium, for providing the original questionnaire, granting permission for its translation and enabling the study.
