Therapeutic targets

## ABSTRACT

The hemoflagellate protozoan, *Trypanosoma cruzi*, mainly transmitted by triatomine insects through blood transfusion or from mother-to-child, causes Chagas' disease. This is a serious parasitic disease that occurs in Latin America, with considerable social and economic impact. Nifurtimox and benznidazole, drugs indicated for treating infected persons, are effective in the acute phase, but poorly effective during the chronic phase. Therefore, it is extremely urgent to find innovative chemotherapeutic agents and/or effective vaccines. Since piplartine has several biological activities, including trypanocidal activity, the present study aimed to evaluate it on two *T. cruzi* strains proteome. Considerable changes in the expression of some important enzymes involved in parasite protection against oxidative stress, such as tryparedoxin peroxidase (TXNPx) and methionine sulfoxide reductase (MSR) was observed in both strains. These findings suggest that blocking the expression of the two enzymes could be potential targets for therapeutic studies.

## Introduction

Chagas' disease, caused by the parasite *Trypanosoma cruzi*, is an endemic illness in Latin America, mainly prevalent in

Brazil, Argentina, Chile, Colombia, and Venezuela. The current treatment for Chagas' disease is based on benznidazole and nifurtimox, which are effective against acute infections, but poorly effective during the chronic phase. In Brazil, nifurtimox had its production and use discontinued. In this context,

**Fig. 1 – Chemical structure of piplartine.**

major efforts are necessary to identify new targets and develop novel trypanocidal drugs.<sup>1–5</sup>

Phytochemical studies of *Piper* species have led to the isolation of typical classes of secondary metabolites such as amides, terpenes, benzoic acid derivatives, and hydroquinones, lignans, neolignans, and flavonoids.<sup>6–9</sup> Piplartine (Fig. 1) is an amide isolated from *Piper* species. An excellent review described its biological activities,<sup>10</sup> such as cytotoxic, genotoxic, antitumor, antiangiogenic, antimetastatic, antiplatelet aggregation, antinociceptive, anxiolytic, antidepressant, anti-atherosclerotic, antidiabetic, antibacterial, antifungal, leishmanicidal, trypanocidal, schistosomicidal, and larvicidal activities.<sup>11–19</sup> Administration of piplartine inhibited solid tumor development in mice transplanted with Sarcoma 180 cells and histopathological analysis showed that liver and kidneys of treated animals were only slightly and reversibly affected.<sup>20</sup> Anticancer activity of piplartine was reinforced when it reduced human glioblastoma (SF-295) and colon carcinoma (HCT-8) cell viability.<sup>21</sup> Acute toxicity studies performed in rats and mice treated with different piplartine doses by oral route demonstrated no obvious clinical alterations.<sup>22</sup> Viability assay carried out against *T. cruzi* epimastigote forms demonstrated growth inhibition higher than that observed with benznidazole,<sup>23</sup> and activity against *Leishmania donovani* was observed, with considerable reduction in parasitic burden and spleen weight *in vivo*.<sup>24</sup>

The low systemic cytotoxicity of piplartine associated with activity against trypanosome cells brought new questions about the possibility of its use as a trypanocidal drug. Therefore, the objective of this study was to evaluate protein expression changes in response to piplartine treatment on the epimastigote form of *T. cruzi*. The capacity of the parasite to grow, associated to high level of cells obtained, allow for performing differential proteomic and mass spectrometry assays. The obtained results are consistent with those described in the literature and may contribute with future similar analysis using other forms of *T. cruzi*.

In this paper, two-dimensional gel electrophoresis (2-DE) and mass spectrometry were used to identify different expressed proteins as a result of piplartine effect on two *T. cruzi* strains, Y<sup>25</sup> and Bolivia,<sup>26</sup> respectively.

## Materials and methods

### Piplartine isolation

Isolation of piplartine from *Piper tuberculatum* leaves was carried out according to a methodology previously published.<sup>23</sup> Briefly, specimens of *Piper tuberculatum* were cultivated from seeds under greenhouse conditions at the Institute of Chemistry, Universidade Estadual Paulista, Araraquara, São Paulo State, Brazil. Plant material was collected in May 2005 and identified by Dr. Guillermo E. D. Paredes from Universidad Pedro Ruiz Gallo, Kambayacheque, Peru. Voucher (Cordeiro-1936) was deposited at the herbarium of the Institute of Biosciences, Universidade de São Paulo, São Paulo, São Paulo State, Brazil.

Shade-dried and powdered leaves of *P. tuberculatum* (200 g) were extracted with ethyl acetate (Synth) and methanol (Synth) (9:1), for three weeks at room temperature. After filtering, the solvent was evaporated under reduced pressure to yield crude extract (11 g). Crude extract (10 g) was subjected to chromatography column over silica gel 60 (70–230 mesh, Merck) and eluted with hexane (Synth) and ethyl acetate (Synth) (0–100% ethyl acetate), and ethyl acetate (Synth) and methanol (Synth) (0–100% methanol) to afford 12 fractions (E1–E12). Fractions E6 and E7 (2.17 g) was further purified by chromatography column over silica gel 60 (70–230 mesh, Merck) and eluted with hexane (Synth) and acetone (Synth) (9:1) to provide 21 fractions (F1–F21), including piplartine (fraction F11, 532 mg). Structure of piplartine was identified by <sup>1</sup>H and <sup>13</sup>C NMR spectra analysis.

### *Trypanosoma cruzi* cell viability assay

Epimastigote forms (Y and Bolivia strains) were maintained in Liver Infusion Tryptose (LIT) medium (68.4 mM NaCl; 5.4 mM KCl; 56.3 mM Na<sub>2</sub>HPO<sub>4</sub>; 111 mM Dextrose; 0.3% Liver Infusion Broth; 0.5% Tryptose)<sup>27</sup> and the cells were harvested during the exponential growth phase. The parasites (1 × 10<sup>7</sup> cells/mL) were treated for 48 h in LIT at 28 °C with 13.7 µM (Y strain) and 10.5 µM (Bolivia strain) piplartine, which corresponds to half of IC<sub>50</sub>/72 h previously determined for this compound. Triplicates of treated and control (without piplartine) parasites were prepared. Calculated IC<sub>50</sub> in 72 h of experiment for piplartine in Y and Bolivia strains were 27.45 µM and 20.95 µM, respectively. For Balb/c macrophages IC<sub>50</sub> was 305.79 µM. Safety index was 11.14 and 14.59, in comparison with piplartine IC<sub>50</sub> for Y and Bolivia strains, respectively (data not published). The chosen concentration of the piplartine for 2DE-DIGE tests was half the IC<sub>50</sub> previously determined, since the intention was to induce protein expression changes, maintained considerable number of viable parasites.

### Sample preparation, labeling and two-dimensional electrophoresis

Treated and control epimastigotes parasites from both strains were centrifuged at 3000 × g for 5 min at 4 °C, the pellet was washed three times with tryps wash buffer (100 mM NaCl, 3 mM MgCl<sub>2</sub>, 20 mM Tris-HCl, pH 7.5) and incubated in

**Table 1 – Sample schematic labeling with Cy Dye DIGE kit.**

|------------------|---|---|---|
| GEL 1            | Pool (50 µg of proteins + 1 µL of Cy2)  | Control 1 (50 µg of proteins + 1 µL of Cy3) | Treated 1 (50 µg of proteins + 1 µL of Cy5) |
| GEL 2            | Pool (50 µg of proteins + 1 µL of Cy2)  | Control 2 (50 µg of proteins + 1 µL of Cy5) | Treated 2 (50 µg of proteins + 1 µL of Cy3) |
| GEL 3            | Pool (50 µg of proteins + 1 µL of Cy2)  | Control 3 (50 µg of proteins + 1 µL of Cy3) | Treated 3 (50 µg of proteins + 1 µL of Cy5) |
| GEL 4            | Preparative (gel to cut the spots)<br>(500 µg of proteins of all samples applied in the experiment-control and treated triplicates) |   |   |

lysis buffer (7 M Urea, 2 M Thiourea, 4% CHAPS, 40 mM Tris, 0.1 mg/mL PMSF; 1 M DTT, 1 mg/mL Pepstatin, 10 mg/mL Aprotinin and 10 mg/mL Leupeptin; all enzyme inhibitors from Sigma-Aldrich) for two hours. Protein extraction was performed using three independent biological replicates of each sample (treated and control). To obtain the soluble protein fraction, the cell lysate was centrifuged at 14,000 × g for 10 min at 4°C and the protein content was determined using the Bradford method.

Each fraction (50 µg of protein of control and of treated triplicates) was marked with DIGE Kit (GE Healthcare) according to Table 1. Briefly: DIGE uses direct labeling of proteins with fluorescent dyes (known as CyDyes: Cy2, Cy3, and Cy5) prior to IEF (isoelectric focusing). Dye concentrations are kept low, such that approximately one dye molecule is added per protein. The important aspect of the DIGE technology is its ability to label two or more samples with different dyes and separate them on the same gel, eliminating gel-to-gel variability. This makes spot matching and quantitation much simpler and more accurate. Cy2 is used for a normalization pool created from a mixture of all samples in the experiment. This Cy2-labeled pool (50 µg of protein of all samples applied in the experiment-control and treated triplicates) is run on all gels, allowing spot matching and normalization of signals from different gels.<sup>28-32</sup> The label proteins were then solubilized in the DeStreak following the manufacturer instructions (GE Healthcare). Each strip was rehydrated with the sample solution for 20 h at room temperature and the proteins were separated over immobilized linear pH 3–10 gradients (IPGphor system, GE Healthcare) using the following protocol: 200 V/12 h, 1000 V/1000 Vh, 8000 V/8000 Vh, 8000 V/20,000 Vh. The pH wide range was applied to obtain the largest number of protein differential expression. The strips were incubated for 15 min in 5 mL of equilibrate buffer (6 M uréia, 50 mM Tris-HCl 1.5 M, pH 8.8, 30% glicerol, 2% SDS, 1% bromophenol blue) containing 50 mg DTT, followed by a second incubation for 15 min in 5 mL of the same buffer containing 125 mg iodoacetamide.

Second dimension separation was performed by 12.5% SDS-PAGE polyacrylamide gels. Gels were run in a SE 600 Ruby (GE Healthcare) at 10 mA/gel for 45 min and then at 30 mA/gel until the end of the gel was reached and 100 W and 600 V. Molecular mass markers were prepared according to the instructions of manufacturer (GE Healthcare) and applied to filter paper before positioning the strips. The gels were scanned in Typhoon Variable Mode (GE Healthcare) and detected spots were quantified and analyzed with the Image Master Platinum software (GE Healthcare). The differential expression analysis was performed comparing the treated and control groups by the Student's t test (>1.3 fold and p ≤ 0.05).

The cut-off limit employed was based on statistically significant differences (p ≤ 0.05).

Preparative gels (containing 500 µg of protein of control and treated triplicates) were stained with Coomassie colloidal as follows: fixation in 45% v/v ethanol and 10% v/v acetic acid for 15 min, washed in deionized water and the addition of 0.1% w/v Coomassie brilliant blue G (Sigma-Aldrich) overnight. The gels were destained with 40% v/v ethanol and 10% v/v acetic acid until visualization of spots. Ten spots were manually excised from preparative gel, being five spots, which protein were more expressed than control, and five spots which treated presented more expression.

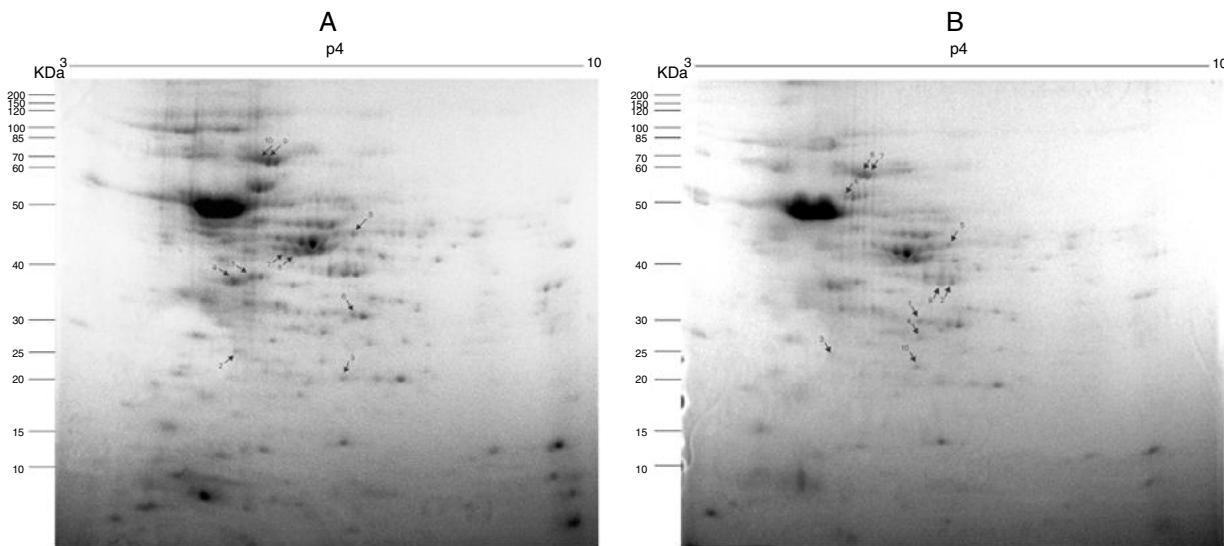

#### Gel *in situ* trypsin digestion and mass spectrometry analysis

The gel spots corresponding to tagged-protein were excised and destained with 50% acetonitrile/0.1 M ammonium bicarbonate pH 8.0. Gels were dehydrated with neat acetonitrile and vacuum dried for 30 min. Gels were swollen with 0.5 µg of modify trypsin (Promega) in 20 µL of 0.1 M ammonium bicarbonate pH 8.0, and the gels were covered by adding 100 µL of 0.1 M ammonium bicarbonate pH 8.0 for 22 h at 37°C. Trypsin hydrolysis was stopped with 5 µL of formic acid. The tryptic peptides were extracted and desalting in microtip filled with POROS 50 R2 (PerSeptive Biosystems) previously equilibrated in 0.2% formic acid and eluted with 60% methanol/5% formic acid for mass spectrometry analysis. Samples were diluted in matrix CHCA 5 mg/mL (alfa-cyano-4-hydroxicinnamic acid, Sigma) with 50% acetonitrile/0.1% TFA (trifluoroacetic acid) and 2–3 µL were deposited on MALDI plates using drop dried method. Mass spectrometry analysis was performed in MALDI-TOF/TOF (AXIMA performance, Kratos-Shimadzu) and the MS/MS spectra of tryptic peptides were submitted directly to MASCOT program against the NCBIInr and local trypanosomatids databases.

#### Results

Several *T. cruzi* proteomic studies have been performed to generate 2DE protein maps of different life cycle stages, to study development-induced changes, identify proteins involved in drug resistance and effects of trypanocidal agents.<sup>33-36</sup>

Fig 2A and B, from Y and Bolivia strains, respectively, show the 10 protein spots differently overexpressed in the cells, being five spots in control (Tables 2 and 3, column "control", spots 1–5), and five spots in treated condition (Tables 2 and 3, column "treated", spots 6–10).

**Fig. 2 – Preparative 2-DE gel image of *T. cruzi* (A. Y strain; B. Bolivia strain) treated with piperazine from *P. tuberculatum* and control. IEF was performed with 500 µg of soluble protein from the parasites using 13 cm strips with a pH range of 3–10. SDS-PAGE was performed with 12.5% polyacrylamide gels, which were stained with Colloidal Coomassie Blue. Arrows indicate modulated proteins of controls and after treatment with the compound; numbers refer to spot identification in Tables 1 and 2, respectively.**

The differential approach using *T. cruzi* cells demonstrated tryparedoxin peroxidase, involved in oxidative stress response, had important decreased expression in treated (that is, more expressed in control), as showed in Tables 2 and 3. It was possible to observe two spots differentially expressed by Y strain, with reduction of 2.194 and 2.349 folds (Table 2, spots 2 and 3); and two spots by Bolivia strain, with reduction of 1.310 and 1.982 folds (Table 3, spots 1 and 4).

Methylthioadenosine phosphorylase (MTAP, Table 2, spot 6 and Table 3, spot 2) catalyzes the reversible phosphorolytic cleavage of methylthioadenosine, a by-product of the polyamine biosynthesis, producing methylthioribose-1-phosphate (MTRP) and adenine.<sup>37</sup> Interestingly, in the Bolivia strain, MTAP was identified in spots 2 and 9, one overexpressed (spot 9) and the other (spot 2) representing reduction of the expression. In Fig. 2B, it is possible to observe that these spots presented small shift in gel and should represent a post-translation modification, suggesting that this mechanism can regulate the expression of this member.

Some studies demonstrated the interaction between tryparedoxin and cystathione  $\gamma$ -lyase (CGL),<sup>38</sup> although the enzyme found in our experiment was cystathione  $\beta$ -synthase (CBS) (Tables 2 and 3, spots 5). Previous studies in mammal cells demonstrated that CBS and CGL act in the same pathway and are primarily responsible for hydrogen sulfide biogenesis.<sup>39</sup>

Enzyme D-isomer specific 2-hydroxyacid dehydrogenase, whose expression levels were altered only in the Bolivia strain (Table 3, spot 3), was one of the proteins identified in the present work. This enzyme is responsible to catalyze the NAD-dependent oxidation of R-lactate to pyruvate and is part of the detoxification pathway of methylglyoxal (dependent of glyoxalase I, glyoxalase II and low molecular mass thiols) in trypanosomatids, and data from *Trypanosoma conorhini*

and *Crithidia fasciculata* showed activation in the presence of cysteine.<sup>40</sup> Altogether, these data strongly suggest a redox regulation of this enzyme in trypanosomatids.

Other protein overexpressed only in the Bolivia strain treated with piperazine was methionine sulfoxide reductase (MSR, Table 3, spot 10). Several amino acid residues were susceptible to oxidation such as cysteine, histidine, tryptophan, tyrosine and methionine.

Proteomics studies usually identified proteins highly expressed such as chaperones, structural and ribosomal proteins and others. In the present work, it was possible to observe heat shock protein 70 and tubulin differentially expressed (Tables 2 and 3).

## Discussion

Various articles explored the activity of different compounds against Y and Bolivia *Trypanosoma cruzi* strains, in special comparing benznidazole activity. Alves and collaborators found higher IC<sub>50</sub> of benznidazole for Y (11.77 µg/mL) compared to Bolivia (0.99 µg/mL) strain. The natural extracts tested showed moderate activity against Bolivia strains, while in Y strain there was satisfactory activity.<sup>41</sup> In other studies, Bolivia strain proved to be more resistant to benznidazole than Y strain. Kohatsu and collaborators observed an IC<sub>50</sub> almost three times higher in Bolivia than in Y strain and demonstrated that this compound increased the expression of the mitochondrial tryparedoxin peroxidase only in Y strain.<sup>42</sup> Additionally, Bolivia strain was more resistant to treatment of two nitrofurans derivatives (NF and NFOH-121) when compared to Y strain. Also, no changes at mRNA processing levels in the Bolivia strain was observed.<sup>43</sup> Mice infected with Y and Bolivia strains treated with benznidazole demonstrated remarkable

differences in mortality rates. All groups infected with the Y strain (treated and non-treated) presented 100% survival. However, only 60% survival was observed in the group infected with the Bolivia strain, while non-treated mice had 100% survival. These findings indicated that treatment with benzimidazole could be detrimental to animals infected with the Bolivia strain.<sup>44</sup> Altogether, these results reinforce that wide genetic heterogeneity of *T. cruzi* strains affect the response against trypanocidal compounds. Our findings showed similar proteome variations in both strains, altering the expression of proteins involved in oxidative stress response. In other hands, two proteins presented protein expression variations only in the Bolivia strain, D-isomer specific 2-hydroxyacid dehydrogenase and methionine sulfoxide reductase.

Raj and co-workers<sup>22</sup> identified 12 potential piplartine targets using differential proteomics approach on two human cell lines, bladder carcinoma and osteosarcoma. Interestingly, these authors identified various proteins involved in stress oxidative response such as glutathione S-transferases and peroxiredoxin. In addition, it was found that piplartine can interact directly with purified recombinant glutathione S-transferase p1 (GSTp1), inhibiting the enzyme activity and decreasing the levels of reduced glutathione. These actions led to increase of oxidized glutathione levels in tumor cells. These data suggest that piplartine can interact directly with components of the oxidative stress response in trypanosomatids cells. Tryparedoxin peroxidase presents crucial role in the regulation of the parasite ROS levels and it is important to highlight the importance of this enzyme as Chagas' disease drug target.<sup>45</sup>

Mitochondrial and cytosolic tryparedoxin peroxidase detoxify peroxynitrite, hydrogen peroxide and small hydroperoxide organic compounds. Ascorbate heme-dependent peroxidase occurs in the endoplasmic reticulum and presents action against hydrogen peroxide. Other enzymes that act against oxidizing agents are the superoxide dismutases (SOD) occurring in the cytosol, mitochondria and glicosoma and work in the detoxification of superoxide.<sup>46</sup>

The main results obtained could be explained by potential interaction among tryparedoxin peroxidase and several other proteins, which are differentially expressed and identified. Piñeyro and co-workers<sup>38</sup> using proteomic approaches described potential interactions between tryparedoxin 1 (*TcTXN1*) and tryparedoxin peroxidase in vitro and in vivo. Methylthioadenosine phosphorylase (MTAP) is responsible to catalyze the reversible phosphorolytic cleavage of methylthioadenosine, a polyamine biosynthesis subproduct, producing methylthioribose-1-phosphate (MTRP) and adenine. In mammal cells, MTAP is redox regulated and can be inactivated by specific oxidation of two conserved cysteines to sulfenic acid, and it should be pointed out that these amino acids were conserved in *T. cruzi* protein.<sup>35</sup>

Therefore, two hypotheses for the difference in MTAP expression following piplartine treatment can be postulated: first, the direct interaction between tryparedoxin and tryparedoxin peroxidase was affected, modifying MTAP levels. These results suggest a secondary role of piplartine in polyamines metabolism. Secondly, redox unbalancing caused for tryparedoxin peroxidase change the expression of MTAP. Since for the Bolivia strain two different spots (2 and 9) were iden-

tified, one overexpressed (spot 9) and other (spot 2) with down-expression, and these spots presented little shift in gel probably representing a post-translation modification. This mechanism could regulate the expression of this enzyme.

*T. cruzi* appears to be the first protist proven to have two independent pathways for cysteine production; sulfur-assimilation from sulfate and transsulfuration from methionine via cystathionine. Extracellular L-cysteine, but not L-cystine, has been shown to be essential for growth of the *T. brucei* bloodstream form. Trypanosomes require cysteine not only for protein biosynthesis, but also for formation of trypanothione and glutathione. They may require multiple cysteine acquiring pathways to ensure this amino acid is available to fulfill the needs of their redox metabolism.<sup>38</sup> Therefore, it is possible to correlate tryparedoxin peroxidase, cystathionine beta-synthase and redox balance. Recently, the same interactome approach was used to demonstrate the partners of *T. cruzi* tryparedoxin II.<sup>40</sup>

Oxidation of methionine to methionine sulfoxide affects the biological function of oxidized proteins.<sup>47</sup> Consequently, the occurrence of a system for reducing methionine sulfoxide to methionine is important for cell integrity and its reaction is present in virtually all organisms.<sup>48,49</sup> Therefore, the presence of a system for reducing methionine sulfoxide to methionine guarantees cell integrity and is present in virtually all organisms.<sup>38,50</sup> Methionine sulfoxide reductase (MSR) protects the organism from oxidative stress and is involved with resistance against biotic and abiotic stress in plants and animals.<sup>38,51</sup> Arias and co-authors<sup>52</sup> studied MSR production in *T. cruzi* and *T. brucei*, indicating a crucial function of this enzyme in the redox metabolism in trypanosomatids and could help the parasites to face oxidative stress. This enzyme is not directly involved in the removal of oxidizing agents, but act mainly in repairing oxidized proteins, maintaining cellular functionality. They found that the reversal of the oxidized state of MSR recombinant is dependent on the presence of reduced tryparedoxin (TXN), probably reducing substrate of the MSR.<sup>52</sup>

## Conclusion

The oxidative stress response is an important defense of *T. cruzi* against the host immune system and other mechanisms of parasite clearance. Therefore, activity molecules able to interfere in this parasitic metabolism represent a potential therapeutic target in Chagas' disease. The DIGE technology eliminating gel-to-gel variability improved the obtention of protein spots. Altogether, our results suggested that piplartine activity in trypanosomes promoted imbalance of some important enzymes related to redox metabolism in these parasites. It should be further investigated whether these enzymes could serve as potential biomarkers to evaluate disease treatment.
