Abstract Leprosy is an infectious disease with chronic evolution, caused by *Mycobacterium leprae*, an acid-fast bacillus that mainly affects the skin and peripheral nervous tissue. Many of the clinical manifestations of leprosy can mimic connective tissue diseases. The authors present the case of a 49-year-old woman who had been treated for four years for systemic lupus erythematosus in a rheumatological service. Skin biopsy of a plaque on the inguinal region was compatible with borderline lepromatous leprosy associated with a type 1 lepra reaction. The patient is undergoing treatment with multibacillary multidrug therapy, showing clinical improvement.

Case report

A 49-year-old woman reported pain in the interphalangeal joints and lower limbs, a skin rash, and alopecia; all symptoms persisted for four years. She was being

treated for systemic lupus erythematosus with hydroxychloroquine, azathioprine, methotrexate, and prednisone. On physical examination, she presented generalized erythematous plaques, and infiltrated areas on the trunk, on the ears, and fingers, as well as diffuse non-healing alopecia (Figs. 1 and 2).

She presented 24-hour proteinuria within normal limits, positive ANA (1:320, centromeric dotted nuclear pattern), positive anti-cardiolipin IgM antibodies, and anti-SM and anti-double helix DNA, both negative.

What is your diagnosis?

- a) Subacute lupus

She also presented paresthesia of the lower limbs, and thickening and pain on palpation of the left ulnar and left external sciatic popliteal nerves.

The bacilloscopy of the ear and two trunk lesions was positive (smear index: 3.33). Histopathology of the plaque in the

inguinal region showed an epidermis with hyperkeratosis; in the dermis, edema and a perivascular, periadnexal, and interstitial mild inflammatory infiltrate composed of lymphocytes, histiocytes, plasmacytes, epithelioid cells, and sparse giant Langhans cells, involving the subcutaneous tissue, adipocytes and septa. Wade staining showed a large number of intracellular acid-fast bacilli, grouped in globi, fragmented and granular (Fig. 3A and 3B). PAS staining did not show thickening of the basal membrane, and no mucin was observed in the Alcian blue staining. In light of the histopathological alterations, a diagnosis of borderline lepromatous leprosy was made in association with type 1 lepra reaction. The patient denied having undergone previous treatment for leprosy and reported that a son-in-law had received anti-leprosy treatment. Multibacillary multidrug therapy and prednisone 60 mg/day were initiated for treating the symptoms and neural lesions. After 30 days of treatment, the patient presented significant improvement (Fig. 4).

Discussion

Leprosy is a chronic contagious infectious disease, caused by *Mycobacterium leprae*, an acid-fast bacillus, with tropism for Schwann cells and the reticuloendothelial system. The bacillus mainly affects the skin and peripheral nervous tissue.¹ The ability of *M. leprae* to regulate cytokine pro-

duction and induce Th1 or Th2 responses contributes to the variety of clinical presentations of the disease.²

Rheumatological manifestations are observed in 64% to 77% of patients with multibacillary leprosy, especially when presenting lepra reactions.³ Rheumatological symptoms were observed in 41.8% of the patients with lepromatous leprosy; in 23.6% of those with tuberculoid borderline; in 18.2% of those with borderline forms; and in 16.4% of those with borderline lepromatous type.⁴

Positive ANA can be observed in 3% to 34% of leprosy patients. Titers are generally low, and the speckled and homogeneous patterns are the most common.⁵ Rheumatoid factor, anti-CCP, ANCA, anti-cardiolipin, and antiphospholipids have been observed in varying percentages in patients with the different forms of leprosy.⁶⁻⁸ Non-scarring alopecia, especially in patients with the lepromatous leprosy, has already been described.⁹

The different clinical manifestations of leprosy pose a diagnostic challenge, since they can mimic other diseases, including autoimmune disorders. The difficulty of diagnosing leprosy early can increase the chance of transmission and cause deformities secondary to peripheral nerve involvement.¹⁰
