

Deaths from abdominal trauma: analysis of 1888 forensic autopsies

Óbitos por trauma abdominal: análise de 1888 autopsias médico-legais

POLYANNA HELENA COELHO BORDONI¹; DANIELA MAGALHÃES MOREIRA DOS SANTOS²; JAISA SANTANA TEIXEIRA²; LEONARDO SANTOS BORDONI²⁻⁴.

ABSTRACT

Objective: to evaluate the epidemiological profile of deaths due to abdominal trauma at the Forensic Medicine Institute of Belo Horizonte, MG - Brazil. **Methods:** we conducted a retrospective study of the reports of deaths due to abdominal trauma autopsied from 2006 to 2011. **Results:** we analyzed 1.888 necropsy reports related to abdominal trauma. Penetrating trauma was more common than blunt one and gunshot wounds were more prevalent than stab wounds. Most of the individuals were male, brown-skinned, single and occupationally active. The median age was 34 years. The abdominal organs most injured in the penetrating trauma were the liver and the intestines, and in blunt trauma, the liver and the spleen. Homicide was the most prevalent circumstance of death, followed by traffic accidents, and almost half of the cases were referred to the Forensic Medicine Institute by a health unit. The blood alcohol test was positive in a third of the necropsies where it was performed. Cocaine and marijuana were the most commonly found substances in toxicology studies. **Conclusion:** in this sample, there was a predominance of penetrating abdominal trauma in young, brown and single men, the liver being the most injured organ.

Keywords: Autopsy. Forensic Medicine. Homicide. Abdominal Injuries.

INTRODUCTION

Deaths from external causes represent the second leading cause of mortality in Brazil and the main cause when considering individuals under the age of 351. Due to the predominance in young and productive people, external causes are the main factors responsible for potential years of life lost in Brazil^{1,2}. Central nervous system injuries account for about half of deaths from trauma, and blood losses by about one-third³. Hemorrhage is the most common cause of avoidable death in patients treated with trauma⁴. Injuries to abdominal structures are an important source of bleeding and are pose special medical interest, since they present great practical difficulties for adequate diagnosis and eventual therapeutic approach, especially when there are other associated lesions^{4,5}. This is because almost half of the bleeding in the peritoneal cavity or retroperitoneum manifests itself with few or no symptoms.

In addition, the accuracy of abdominal physical examination is low and the level of consciousness produced by hemorrhages or by the association of abdominal trauma (AT) with traumatic brain injury and/or effects of central nervous system of previously consumed substances make the adequate clinical examination even more difficult⁶⁻⁸. Therefore, it is emphasized that the absence of abdominal pain or signs of peritoneal irritation on physical examination does not exclude the presence of abdominal organs injuries⁹. Even in cases of AT with death, there are no external lesions indicative of this type of trauma in up to 31% of cases¹⁰. These limitations together result in preventable deaths from undiagnosed abdominal injuries, even considering that the actual need for laparotomies due to closed abdominal trauma is around 5%⁶.

AT can be classified basically into two types: penetrating (open) and blunt (closed)¹¹. The penetrating is the one in which the entry of the aggressive agent

1 - Civil State Police of Minas Gerais, Coroner's Office, Ribeirão das Neves, MG, Brazil. 2 - José Bonifácio Lafayette de Andrada Foundation, Faculty of Medicine, Barbacena, MG, Brazil. 3 - Civil State Police of Minas Gerais, Forensic Medicine Institute, Belo Horizonte, MG, Brazil. 4 - University of Ouro Preto, School of Medicine, Ouro Preto, MG, Brazil.

into the peritoneal cavity occurs, in most cases a firearm projectile (gunshot) or a laminated object (stabbing) and it exerts its effects directly over the viscera. In this case, the organs most affected are the small intestine, colon and liver¹¹. In blunt AT there is no penetration of the aggressive agent into the peritoneal cavity. The effects of the offending agent in this case are transmitted to the viscera through the abdominal wall, or by kickback and deceleration. The prevalence of abdominal viscera lesions in cases of blunt trauma is around 13%, the spleen and liver being the most damaged structures in this situation⁹.

Considering the global epidemiology of AT, the majority of cases treated in hospital units are blunt trauma, but in regions with high homicide rates, such as large Brazilian cities and their metropolitan regions, penetrating trauma may be more frequent^{8,9,11,12}. Around 75% of cases of blunt AT result from traffic accidents, with assaults accounting for 15% and falls for the rest⁹. The mean mortality rate of AF due to gunshot wounds, of around 7%, is higher than in cases of stabbing injuries and blunt trauma¹³.

In recent years, in parallel with the increase in intentional and unintentional interpersonal violence in our country, the AT's incidence has also increased^{2,11}. In deaths due to external causes, or in cases that are suspected of being such, a legal medical necropsy is mandatory by our legislation^{14,15}. In these situations, completing the death certificate is a responsibility of the coroner¹⁶. Data from necropsy medical-legal reports can provide important information in the epidemiological study of AT, since unlike the information available in the Mortality Information System (MIS) of the Ministry of Health, it contains a detailed description of the lesions found, as well as other important information on the context of death, such as data on the search for alcohol content and other substances consumed prior to death, such as illicit drugs. In addition, despite advances in imaging studies, necropsy remains the "gold standard" for the confirmation of clinical and surgical diagnoses, including AT cases⁷. The ideal, therefore, for a complete epidemiological investigation on mortality by AT and for the other external causes is that medical-legal reports be a source of complementary information to the MIS, as recommended by the World Health Organization^{7,17}.

Considering the importance of AT, as well as the deficiency of national information involving necropsic studies with this cause of death, this research aimed to evaluate its epidemiological profile at the Belo Horizonte Forensic Medical Institute (IML-BH).

METHODS

We conducted a retrospective study, in which were evaluated the reports of deaths from abdominal trauma necropsied in the IML-BH from January 1, 2006 to December 31, 2011. Located in the capital of the state of Minas Gerais, IML-BH is a government department linked to the Civil Police, being responsible for the medical investigation of all deaths due to external causes occurred in the capital of the state and in most of the municipalities of its Metropolitan Region (RMBH). Necropsic forensic investigation of all deaths from violent causes is mandated by federal law in Brazil¹⁴. Belo Horizonte (BH) is the sixth most populous city in Brazil, with an estimated population of 2,513,451 inhabitants for the year 2016¹⁸. Its metropolitan area is the third most populous in the country, with an estimated population of 5,829,921 inhabitants in the year 2015¹⁸.

The deaths analyzed in this study were those whose cause directly involved AT. We also included cases with trauma in other body regions, such as the head, limbs and thorax, as long as associated with AT in the mechanism of death. We excluded cases that presented technical problems in the completion of the reports, the duplicates, the cases whose types of trauma could not be precisely defined, and those in which the death was due to trauma occurring exclusively in other body regions other than the abdomen.

We analyzed data on seasonality (year, month and day of the week), demographics (gender, age, marital status, occupational characteristics, skin color, and residence), deaths characteristics (circumstance, type of trauma, trauma mechanism, signs of medical care) and complementary tests performed (toxicological and blood alcoholic findings). Not all such variables were available in all reports.

We considered that the deceased received medical care prior to death when they came from

health facilities, when they were referred along with medical reports or when they showed signs of recent medical procedures such as vascular punctures, signs of orotracheal intubation, surgical wounds, placement of drains, among others. Even in cases that received medical attention, trauma indexes were not available.

We performed statistical analyzes using the STATA software, version 9.2. We obtained frequency, position and central tendency measurements, and used the Chi-square and Fisher's exact tests for comparison of qualitative variables and the Kruskal-Wallis test for comparison of quantitative ones, in order to evaluate possible associations. The level of significance was set at 0.05.

The project was approved by the Ethics in Research Committee of the Hospital Foundation of the State of Minas Gerais, under the protocol number 23100813.2.0000.5119.

RESULTS

We recovered 1888 reports of fatal victims of abdominal trauma (AT), corresponding to 5.2% of the total necropsies performed at IML-BH in the studied period (2006 to 2011). The underlying cause of death was hemorrhage and its direct complications in 1884 cases, and trauma-related infectious complications in four. Penetrating trauma was more common (78.76%) than blunt trauma (401 cases – Table 1). Of the penetrating trauma cases, gunshot wounds were more prevalent (89.28%) than stabbing wounds (159 cases).

The highest proportion of necropsies occurred on Sundays (23.94%), in January (9.75%) and in 2007 (23.41%). The lowest number of autopsies took place on Fridays (165 cases), in the months of September (128) and in the year of 2010 (209).

The majority of the individuals were male, brown, single, were 49 years old (90.79%), occupationally active, had completed high school as a minimum level of education required to practice their profession and did not reside in the city of Belo Horizonte (Table 1). We highlight the significantly higher proportion of necropsies in males, brown or black, single and residing in Belo Horizonte (BH) related to the deaths due to penetrating trauma compared with

blunt trauma (Table 1). There were also proportionally more men, unmarried and BH residents whose death was related to gunshots when compared with those whose death cause was stabbing (Table 2). The mean age found in the sample was 29.73 ± 12.86 years, and the extremes of age were one and 90 years. The mean age of victims of penetrating trauma was significantly lower (27.87 ± 10.62 years) than that of blunt trauma (36.64 ± 17.32 years) ($p < 0.001$). The mean age of gunshot victims was significantly lower (27.19 ± 10.15 years) than that of stabbed individuals (33.70 ± 12.66) ($p < 0.001$).

Homicide was the most prevalent death (78.55%). Health units sent most of such cases to the IML-BH (47.99%), although most necropsies did not undergo medical procedures prior to death (77.12%) (Figure 1). For blunt trauma, there was a significantly higher proportion of deaths due to traffic accidents (83.29%) and signs of receiving medical assistance prior to death (56.86%) compared to penetrating trauma (Figure 1). There were proportionately fewer individuals coming from residential addresses who died due to gunshots compared with those whose death was due to stabbing (Table 2). Among the homicide cases, we observed a higher percentage of males (92.51%).

The data obtained with complementary exams performed in the AT victims, regarding alcohol and illicit drugs use, can be seen in table 3.

There were proportionally more hepatic and splenic lesions in blunt traumas (315 and 170 cases, respectively) than in the penetrating trauma (1293 and 382 cases, respectively) ($p = 0.000$ for both) (Figure 2). Although the most injured abdominal organ in penetrating trauma was the liver, there were predominantly more lesions in the intestines (853 cases), stomach (351 cases) and blood vessels (312 cases) of individuals victims of penetrating trauma when compared with blunt trauma (75, 17 and 31 cases, respectively) ($p = 0.000$ for all variables). The kidneys were proportionally more affected in cases resulting from stab wounds (17 cases) compared with those related to gunshots (82 necropsies) ($p = 0.04$). Intestinal lesions were more common in gunshot (709 cases) than in stabbing wounds (69 cases) ($p = 0.006$). We observed concomitant lesions in more than one abdominal organ in some individuals.

We observed head injuries in 347 cases and thoracic organ injuries in 1503 individuals. Although the

lungs were the most affected extra-abdominal organs in all death mechanisms, we observed more injuries to the head and heart of the victims of penetrating trauma (346 and 722 cases, respectively) than in the victims of blunt trauma (49 102 cases, respectively) ($p=0.000$ for both) (Figure 3). Even with the presence of these associated lesions, they were not attributed by the coroners as exclusively responsible for the deaths. It is noteworthy that there were concomitant lesions in more than one body segment in some autopsies and that multiple organ lesions were observed in some individuals.

For blunt trauma, in cases of both hepatic and splenic lesions, the limbs' fractures most frequently found were those of lower limbs, especially of the femur (49 cases/15.6% and 24 cases/14.2 %, respectively) and tibia/fibula (39 cases/12.4% and 18 cases/10.6%, respectively).

The mean number of gunshot wounds to the abdomen was 1.33 ± 1.28 , with the median of one entry orifice, first quartile of one, and third quartile of two entry orifices. The highest number of entry lesions observed

in the same individual in the abdomen and/or chest were 15. The mean number of stab wounds was 2.76 ± 4.41 . It is noteworthy that gunshot and stabbing thorax entries were also responsible for abdominal organ lesions.

DISCUSSION

In our sample, penetrating trauma was much more frequent (78.8%) than blunt one. A study carried out with victims of AT submitted to exploratory laparotomy in the city of Florianópolis also found a majority (68.6%) of cases related to penetrating trauma¹⁹. However, these percentages vary when data from different cities and countries are observed. Retrospective studies of AT victims in the Portuguese city of Porto and in Kathmandu, Nepal, indicated that 85.3% and 82.5% were cases of blunt trauma, respectively^{20,21}. The almost inverse percentages observed in these countries when compared with our sample reflect the different circumstances related to AT in each locality. Most cases of IML-BH autopsies were related to homicides (78.6%), especially cases of penetrating trauma, whereas in the Portuguese study, traffic accidents and falls were the most prevalent (76.1%), and in the Nepalese study, traffic accidents were the majority (87.5%), which are more related to blunt trauma^{20,21}. In addition, our sample consisted only of fatal cases, while the Portuguese series also considered those who survived, and penetrating trauma displayed higher average mortality²⁰.

Considering all cases of penetrating trauma that receive medical attention, those due to stabbing are, in general, more frequent than cases related to gunshot wounds¹². However, in the IML-BH sample, as well as in the data from the Florianópolis study¹⁹, it was observed that gunshot wounds were more frequent than stabbing wounds. The IML-BH greater proportion of gunshot wounds among the penetrating traumas is justified by the fact that abdominal injuries gunshots represent up to 90% of the mortality in penetrating AT¹³. By transferring increased kinetic energy to organs and tissues, abdominal trauma due to gunshots results in a mortality rate about eight times higher than that related to stabbing injuries²². Although in the cases of IML-BH the penetrating trauma due to gunshots represented a percentage greater than that found in the Florianópolis study (89.3% and 75.6%, respectively)¹⁹, that study also evaluated patients who survived the trauma (89.8% of those who underwent surgery), which may justify this dif-

ference¹⁹.

The majority of individuals necropsied in IML-BH were male (90.3%), with a mean age of 34 years. In the study conducted in Porto, males were also more prevalent (74.2%) and the mean age was 42.6 years²⁰. The higher male prevalence and the lower mean age observed in our sample are a reflection of the large proportion of homicides and penetrating trauma among the cases of IML-BH, situations in which male and younger victims are more commonly observed². It should be noted that, in the Portuguese series, the most frequent trauma circumstance was traffic accident, which covers a larger age group and a larger female contingent^{2,20}. In a case-control study conducted in the city of Curitiba, it was observed that in deaths due to blunt AT, males accounted for 77.4% of the cases and the mean age observed was 33.2 years²³, results similar to those found in our sample if considered only cases of blunt AT (83.29% men and mean age 36.64 years). In a work involving homicide victims in Cape Town, 90.2% of the cases were men, a percentage practically identical to that of our sample²⁴.

In the period from 2002 to 2012, the number of homicides registered in Brazil increased from 49,695 to 56,337, an increase of 13.4%². In Minas Gerais, homicides increased by 7.1% in the same period². For the year 2012, Belo Horizonte had a total homicide rate of 40.6 per 100 thousand inhabitants, but when considering only homicides in individuals under 29 years, the rate more than doubles (91.9/100 thousand)². The relationship between AT and male gender, especially in cases of gunshot homicides, is due to men being more involved in criminal use of firearms (widely available in our country), in addition to consuming proportionally more alcohol and illicit drugs than women, factors that increase aggressiveness and the adoption of violence-risky behaviors^{2,21}. In 2012, the national rate of 54.3 homicides per 100,000 male residents was about ten times higher than the female rate (4.8/100 thousand)². It is noteworthy that, while women accounted for only 6% of the gunshot victims in our sample, 18.9% were stabbing victims, which may suggest the passionality of assaults against women, which occur frequently in the domestic sphere, where knives are easily accessible to the aggress-

sor²⁵. While almost half of all homicides occur in public spaces, less than a third of female homicides occur in such locations, the victim's home being the site of 27.1% of female homicides²⁵. Such data together may also justify the larger proportion of stabbed individuals coming from their home addresses found in our sample compared with those whose death was related to gunshots.

Only 1.16% of the cases of homicide with AT autopsied in the IML-BH involved blunt trauma. A South African study of victims of blunt trauma homicides showed that, although 20% had some type of abdominal injury, in only 7% there were no significant associated cranial lesions²⁴. Tunisian cases with homicide data from 2005 to 2014 indicated that blunt trauma was the second most common death mechanism (24.8%)²⁶.

Most individuals (90.79%) were up to 49 years of age (about 50% in the age group 18-29 years), which may be related to most individuals being single. The mean age of victims of penetrating trauma in homicides, 27.87 years, was significantly lower than that of injuries resulting from blunt trauma in traffic accidents, 36.64 years, which agrees with the national statistics on mortality from external causes. When considering the deaths of individuals under 29 in Brazil, in 2012, 71.1% were due to external causes, with 38.7% of homicides².

Most of the necropsied had brown skin, both in cases of penetrating trauma (64.8%) and in blunt traumas (51.6%). A study conducted in the city of Salvador with deaths from external causes from 1998 to 2003 indicated that men with brown skin lose more potential years of life due to violence than the black and white population²⁷. Such differences observed in potential years of life lost per 100,000 inhabitants among different skin color groups remained even after age standardization, and brown and black men, in that order, died earlier due to all types of external causes²⁷. Whites tend to have a better average schooling rate than browns and blacks, a better socioeconomic level, better access to health promotion measures and less exposure to violence²⁷.

Weekends concentrate most of the cases of external deaths, especially homicides, in several studies^{24,28-30}. In our sample, where the death circums-

tance was predominantly homicide, almost a quarter (23.9%) of autopsies occurred on Sundays. Epidemiological data on homicides in the state of São Paulo, in Cape Town, South Africa, and in the city of Ilhéus, Bahia, indicated that Sundays also concentrated the highest proportional number of cases (20%, 23.7% and 32%, respectively). This corroborates that the weekend is the period of greatest exposure to risk factors for violence, such as the consumption of alcohol and illicit drugs, as well as the permanence in environments conducive to interpersonal conflicts²⁸. The same reasoning applies to those periods with longer and hotter days, especially January, which concentrated 9.8% of IML-BH cases.

At the Getúlio Vargas State Hospital, in the city of Rio de Janeiro (HGV-RJ), with 1688 patients operated on with blunt AT, the spleen was the most damaged abdominal organ, followed by the liver, intestines (small and large), bladder and the kidneys¹¹. A study in Santa Catarina State patients submitted to exploratory laparotomy indicated splenic lesions twice as frequent as hepatic ones in blunt trauma¹⁹. In the IML-BH data, the liver was the most affected viscera in blunt AT, with the spleen in second, followed by the intestines and large abdominal vessels. Similarly, another necroscopic (Nepalese) study also indicated a higher percentage of hepatic lesions (57.5%) than spleen ones (37.5%)¹⁰. Hepatic lesions produce potentially larger hemorrhages than splenic injuries, and as our casuistry involved only those who died, the considerably higher percentage of liver lesions is explained. A case-control study with victims of blunt AT who received medical care showed that, for most of deaths preceded by hemodynamic instability, there were lesions of massive abdominal viscera²³. The retrospective study with polytrauma patients who presented severe traumatic brain injury demonstrated that the liver was the most affected abdominal viscus in cases with associated AT and signaled that hemodynamic instability at hospital admission indicated a six-fold increased risk for the presence of abdominal viscera lesions compared with patients who were hemodynamically stable⁶. Hemorrhage, with its direct complications, was responsible for almost all deaths in our sample (1884 cases).

In cases of blunt AT necropsied in the IML-BH, femoral fractures were observed in 15.6% of individuals with hepatic lesions and in 14.2% of cases with splenic lesions. Femur fracture was the bone lesion most frequently associated with abdominal viscera lesions in our data, which is widely corroborated by the literature. A systematic review of 10,757 patients with blunt trauma indicated that the concomitant presence of femoral fracture increased the relative risk of visceral abdominal injury by 2.9 times⁹. The risk of abdominal visceral injury increased 58-fold when there were surgical orthopedic lesions in polytraumatized patients with cranio-encephalic trauma⁶.

The proportion of lesions in large abdominal (arterial and venous) vessels observed in our sample, of 8%, was higher than that found in the Rio de Janeiro series in cases operated due to closed AT (0.7%)¹¹, but the severity of volume loss in necropsied cases explains its greater prevalence in our data.

The second most common circumstance of death in the IML-BH data were traffic accidents, with all AT deaths in this group due to blunt trauma. The intestines, especially the small one, are the most damaged abdominal viscera in blunt AT, being affected in up to 3% of the cases^{31,32}. A prospective multicenter American study has indicated that victims of traffic accidents are 1.5 times more likely to present abdominal hollow viscera lesions than in other blunt trauma mechanisms³². In addition, the mortality rate ranges from 15% for small intestine lesions to around 19% for rectal lesions³³. These data, together, corroborate what we observed, a high percentage of intestinal lesions in blunt AT (19%), which reflects large energy transfers in traffic accidents in fatal cases. For cases of blunt trauma with isolated abdominal hollow viscera lesions, the Paraná case-control study indicated that this is a good prognostic factor, even in lesions that require surgical intervention²³. That is, usually in fatal cases of blunt AT, injuries other than those of hollow viscera are responsible for death. We observed this in our sample, where lesions of intestines in blunt AT were generally associated with other visceral lesions, since in none of these cases the cause of death was exclusively determined by intestinal lesions.

Gastric lesions in blunt AT are observed in

up to 1.7% of cases, a low percentage explained by the relatively protected anatomical position of this organ^{33,34}. Although relatively rare, they present high mortality, varying from 28% to 66%³¹⁻³³. This justifies the higher percentage (4%) observed in the IML-BH data, since only fatal cases, naturally more severe, were studied. Because it presents a protected position, a greater transfer of energy is necessary to produce a gastric lesion, and in about 95% of the cases, there are other associated lesions, such as of the spleen and lungs³³⁻³⁵. Like with intestinal lesions, there were no deaths exclusively due to gastric lesions in our data.

The most damaged organs in cases of penetrating AT necropsied in IML-BH were the liver, followed by the intestines, both in gunshot and stabbing victims. Although there are regional variations, the reverse is epidemiologically observed, with intestines more damaged than the liver in this type of trauma^{12,13,19}. A HGV-RJ series with 4478 patients operated on due to penetrating AT indicated that the intestines (duodenum, jejunum, ileum and colon) were the most commonly affected abdominal organs, followed by the liver, stomach and kidneys¹¹. The same was observed in a Florianópolis study¹⁹. Liver lesions by penetrating AT show higher mortality rates than intestinal lesions^{13,36}, reaching 22% in gunshot wound cases and 8% in stabbing ones³⁶, which explains their high prevalence in IML-BH penetrating necropsies. Although the liver was the most commonly injured abdominal organ in penetrating AT in our sample, there were predominantly more lesions in the intestines, stomach and large abdominal vessels of individuals who were victims of penetrating trauma compared with victims of blunt trauma. It is noteworthy that isolated hepatic lesions due to gunshots are not common, these being usually associated with other lesions, particularly the right lung, diaphragm, right kidney and small intestine³⁷. In our sample, 81% of the victims had lung injuries associated with the abdominal trauma.

Abdominal vascular injuries due to penetrating trauma, especially those located in the upper portion of the abdomen, present a high mortality rate because they produce massive hemorrhage and present a high incidence of associated lesions³⁸. The mortality rates of abdominal vascular injuries can reach 53%

in cases of shooting and 32% in cases of stabbing³⁶. The HGV-RJ data showed a low percentage of lesions of large abdominal vessels in open trauma, with only 2.5% of cases presenting lesions of the inferior vena cava and lower percentages with lesions of other important abdominal vessels¹¹. In the Florianópolis study with patients operated on due to penetrating AT, vascular lesions were observed in 5.4% of cases¹⁹. We should emphasize that the series from Rio and Florianópolis involved both patients who died and those who recovered from the surgical procedures. In our sample, we observed lesions of large abdominal arterial or venous vessels in larger proportions (18% of the victims of gunshots and 23% of the victims of stabbing), since the main immediate cause of death in AT is blood loss.

The mean number of gunshot entry wounds that caused lesions to abdominal viscera was 1.3 and the mean of stab wounds was 2.8. Multiple stabbing wounds are found in up to one-third of patients receiving medical care for this type of trauma¹². Since the transfer of kinetic energy to the tissues is much greater in the gunshot injuries¹³, the smaller number of perforations is sufficient to cause serious lesions causing death. One of the consequences of this is that the kidneys, which are retroperitoneal and, therefore, deeper structures, were proportionally more injured in cases resulting from stabbing compared with those related to gunshots.

The proportion of 33.8% positivity in the studied blood alcohol levels in our sample was similar to that found in a retrospective study that used data from all violent deaths occurred in the state of São Paulo in 2006, of 36.9%³⁹. Such data may indicate common cultural traits related to the consumption of this substance among different units of the Brazilian Federation. The mean blood alcohol content in the study from São Paulo, 18dg/L, was higher than that found in our sample, 15.3dg/L, although it involved a larger geographical area and all causes of external deaths³⁹. Another study, based on data from 2042 homicide victims in the city of São Paulo, found a positive reaction to ethyl alcohol in 43% of cases, with an average of 15.5dg/L⁴⁰, practically the same average value of our data. The majority of cases of blunt

AT of the IML-BH presented an average higher alcohol content, of 18.54dg/L. Knowing that such cases were related to traffic accidents, we highlight the probable association between alcohol consumption and this circumstance of death, already widely described in the literature⁴¹. The IML-BH data also showed proportionally more positive cases of alcohol consumption, and with higher averages, 20.4dg/L, in stabbing-related deaths than in gunshot victims, 12.17dg/L, which was also observed in the study with homicide victims in the city of São Paulo⁴⁰. Interpersonal assaults with the use of knives generally involve more passion than the violence related to firearms and, in this context, is related to higher means of alcoholism positivity⁴⁰. Alcohol is the most commonly found substance in forensic toxicology analyzes and is an important risk factor for violent deaths, being directly involved in up to 50% of such deaths^{39,41}. Although alcoholic drunkenness is a syndrome of essentially clinical diagnosis, and non-laboratory, with a blood alcohol content of 15dg/L, most people will present important neurological changes, such as emotional instability, loss of critical thinking, variable memory deficits, sleepiness and motor deficits, among others⁴¹. These effects put the individual at risk for violent behaviors or for negligence with situations of potential risk, such as accidents and assaults^{39,41}.

The drugs most commonly found in IML-BH toxicological investigations were cocaine and marijuana, the most commonly used illicit drugs in Brazil^{42,43}. Similarly, in the study carried out with data from the MIS and IML-BH, which evaluated cases of homicides occurred in Belo Horizonte from 2000 to 2009, it was observed that cocaine was the most common illicit drug⁴³. A meta-analysis of 28,868 toxicological investigations of 30,482 homicide victims in five countries found that cocaine was the most common illicit drug, with 11% of cases, followed by marijuana, with 6%, cocaine being related to an increased risk of death by gunshot wounds⁴⁴. Similarly, in the IML-BH data, there were proportionally more positive results in the toxicology exams of individuals who died due to gunshots compared with those whose death was caused by stabbing wounds. The percentage of cocaine -positive cases in our sample, 40.9%, was higher than

that found in homicide victims in the American city of New York, 31%⁴⁵, almost double the percentage found in homicide victims in the state, 20.9%⁴⁶, and almost quadrupled that found in the meta-analysis with data from five different countries⁴⁴. Although we studied a more specific group of individuals, we highlight the relation between cocaine and violent death, be it in cases of homicide or in cases of accidents or suicides⁴⁶. The meeting of 20 individuals with simultaneously positive toxicological examination for cocaine and marijuana reaffirms the association between these two drugs and violent deaths⁴⁶. The consumption of illicit drugs is an important risk factor for deaths due to external causes, not only due to its effects on the central nervous system and consequent behavioral changes, but also to exposing the user to situations of violence related to the acquisition and commercialization of the substance⁴³. Although there is evidence that Brazilian and Ameri-

can consumption of marijuana is greater than that of cocaine, its stimulating effects on the central nervous system, different from the predominantly inhibitory effects of marijuana, predispose the user to situations of violence^{43,46,47}.

As important limitations of this study, we should highlight that the information was collected from secondary sources and that the information on the detailed history of the deaths' circumstances was not available in the reports evaluated. Moreover, the extrapolation of the conclusions should be considered with care, since the data were obtained from a specific geographic region. There are administrative and technical peculiarities involving the operation of different Legal Medical Institutes in the different Brazilian states and in other countries, which influence which cases are directed to necropsy, how necropsies are performed and how reports are made.

R E S U M O

Objetivo: avaliar o perfil epidemiológico dos óbitos por trauma abdominal no Instituto Médico Legal de Belo Horizonte. **Métodos:** estudo retrospectivo dos laudos de óbitos relacionados a trauma abdominal necropsiados no período de 2006 a 2011. **Resultados:** foram analisados 1888 laudos necroscópicos de trauma abdominal. O trauma penetrante foi mais comum que o contuso, e o decorrente de projéteis de arma de fogo mais prevalente que o relacionado a armas brancas. A maioria dos indivíduos era do sexo masculino, morena, solteira e ativa do ponto de vista ocupacional. A média etária foi de 34 anos. O homicídio foi a circunstância do óbito mais prevalente, seguido dos acidentes de trânsito, e quase a metade dos casos foi recebida no Instituto Médico Legal proveniente de uma unidade saúde. Os órgãos abdominais mais lesados no trauma penetrante foram o fígado e os intestinos, e no trauma contuso foram o fígado e o baço. A pesquisa de alcoolemia foi positiva em um terço das necropsias onde foi realizada. Cocaína e maconha foram as substâncias mais encontradas nos exames toxicológicos. **Conclusão:** nesta amostra houve predominância do trauma abdominal penetrante, em homens jovens, morenos e solteiros, sendo o fígado o órgão mais lesado.

Descritores: Autopsia. Medicina Legal. Homicídio. Traumatismos Abdominais.
