ABSTRACT

PURPOSE: The aim of this study was to describe an experimental surgical technique to be used in the evaluation of bone grafts in rabbits.

METHODS: The operative technique was performed in jaws, with external approach from the labial commissure to the last molar tooth. An incision about 1cm extended forward to the alveolar ridge, followed by exposing the cervical region of the alveolar bone and dental elements was done. Thus, after extraction of first molar with forceps, the tooth socket left was filled with hydroxyapatite. The bone gain was analyzed by histopathological studies.

RESULTS: The histological analyses indicated formed bone surrounding the biomaterial.

CONCLUSION: The experimental model using the tooth socket of the rabbit molar is a feasible procedure for studies of bone grafts.

Key words: Animal Experimentation. Dental Models. Rabbits.

RESUMO

OBJETIVO: Descrever uma técnica cirúrgica em coelhos para avaliação de enxertos ósseos.

MÉTODOS: A técnica operatória consiste numa incisão na topografia da comissura labial até o último molar. Uma incisão de 1cm no rebordo para expor o osso alveolar e a região cervical dos molares. Realizou-se a exodontia com fórceps e o alvéolo é preenchido com hidroxiapatita. Após o tempo de cicatrização é realizada a avaliação histológica.

RESULTADOS: A análise histológica mostrou o novo osso formado rodeando biomaterial.

CONCLUSÃO: O modelo cirúrgico para avaliação de enxertos ósseos utilizando molares de coelhos se mostrou factível.

Descritores: Experimentação Animal. Modelos Dentários. Coelhos.

Introduction

The alveolar bone is modified both in quality and in quantity after tooth extraction¹. The healing process results in a formation of trabecular bone and marrow due significant bone loss, mainly on the walls and inside buccal and lingual/palatine regions².

Various materials are used to prevent such bone loss after tooth extraction, for example: dental implants, physical barriers³, and/or bone grafts⁴.

A variety of bone grafts have been used in maxillofacial surgery. Although a wide variety of bone grafts and implants have been evaluated in various species of experimental animals, there has been little consistency among investigators in the choice of an appropriate animal model⁵⁻⁷. Some researchers are already using tooth socket as a model including the use of dog, rat and rabbit incisors for these studies⁸⁻¹².

The authors describe a new experimental surgical technique using the tooth socket of the rabbit molar useful in the evaluation of bone grafts.

Methods

This study was approved by the Ethics Committee for Use of Laboratory Animals in Research of the Faculty of Medicine of UFRJ, Protocol 076/09.

Pre and postoperatively, the animals were kept in individual cages in a temperature-controlled environment with water *ad libitum* and standardized feed.

For the development of the surgical procedure were used six rabbits (*Oryctolagus cuniculus*) New Zealand, white, male, weighing 2.5 kg to 3.0 kg with a mean age of ten months, operated and maintained in the Center of Experimental Surgery, School of Medicine, UFRJ.

We used intravenous general anesthesia with the combination of benzodiazepines (5mg/kg) and 10% ketamine (25mg/kg). The rabbits were anesthetized with lidocaine 1%, the maximum dose of 9mg/Kg, with infiltration trunk to block the inferior alveolar and the labial commissure.

The surgery was performed in the jaw with an external approach incision, from the labial commissure to the last molar tooth, by about 1cm in length (Figure 1), prior to the alveolar ridge. Then the cervical region of the teeth was exposed, as well as the alveolar bone (Figure 2). Thus, after extraction of first molar with forceps, a bone store average of 3 mm (mesio-distal) X 3mm (buccolingual) X 12mm (cervical-apical) was found, with the average size of the walls buccal, lingual, and mesial distal with approximately 1.5 mm (Figure 3). Subsequently, the bone graft (biomaterial) was placed in the tooth socket with a Molt surgical curette. In the present work the material chosen for the graft were beads of hydroxyapatite (HA) (Figure 4). The wound closure was done in layers with sutures of the mucosa, muscle and subcutaneous tissue with polyglycolic acid 4-0 and the skin with 4-0 monofilament nylon.

Postoperative analgesia was performed using intramuscular ketoprofen at a dose of 1mg/kg every 24 hours, and enrofloxacin at a dose of 10 mg once daily for five days.

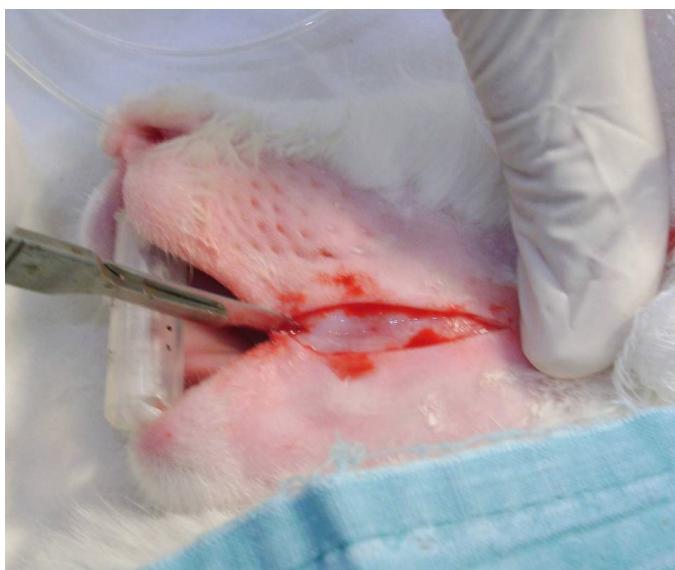

FIGURE 1 – Extraoral approach with the skin incision.

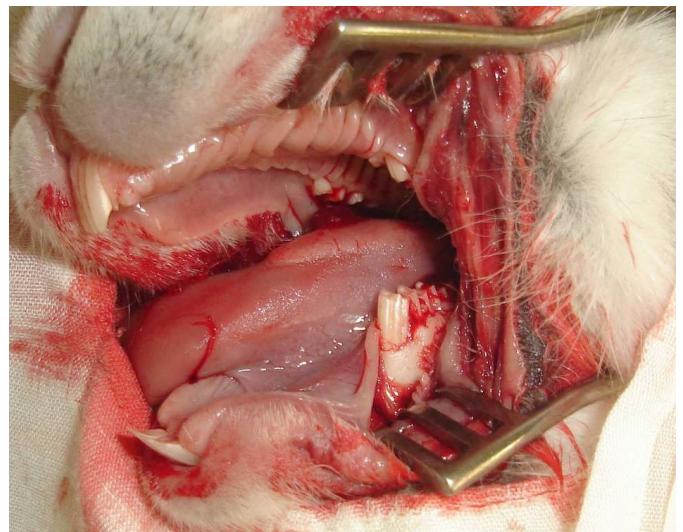

FIGURE 2 – Exposure of the cervical region of teeth and alveolar bone.

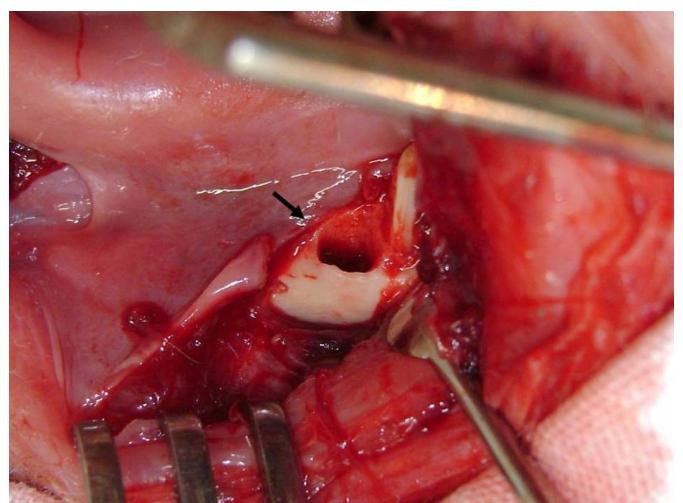

FIGURE 3 – Tooth socket of the first molar.

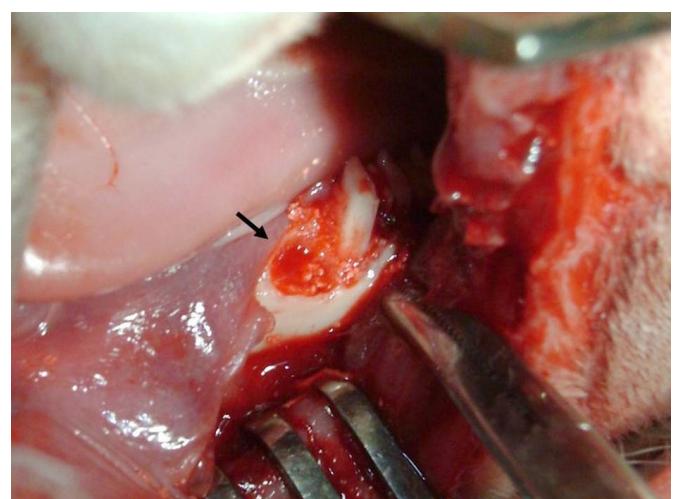

FIGURE 4 – Implantation of the bone graft in the tooth socket.

Results

The former histological results showed a fibrous connective tissue surrounding the biomaterial (HA) and a new bone formation, sparse inflammatory infiltrate with few multinucleated giant cells.

In all animals, during the tooth extraction there was no root fracture and it was feasible a primary wound closure. It was also not observed wound dehiscence, infection or loss of grafting material.

Discussion

Relevant researches have been undertaken with the aim of discussing the use of more appropriate materials for effective repair of bone lesions in surgical animal model. One of the most known surgical models is the critical bone defect, which means to make bone impairment with the smallest dimensions that cannot be repaired spontaneously during the lifetime of the animal⁹. However, as most studies have limited duration it should be considered as a critical repair of bone defects that do not suffer during the research¹³. The healing of the alveoli is a well known biological event and cannot be considered as a critical defect in experimental studies.

Schmitz and Holliger⁶, in their experiments, described some models of bone lesions in different sites such as the calvaria and mandible without reporting the changes in the jaw bone of rabbits⁹. Bone defects caused in the region of the mandible body 15 x 10mm in rabbits were used for studies of bone grafts with the aid of fixing^{10,14}. A surgical model with a bone store was proposed to be used to evaluate bone graft without fixation and protection using the alveoli of the molars of the rabbit.

Other researchers have used the rabbit incisor for their studies of biomaterials. However, this roots have large curvature and hampers their extraction^{9,10}. The use of extra-oral access decrease the surgical difficulty and the biomaterial can be used up at four teeth sockets with similar proportions in the same animal and resulting in less amount of animals required.

The dental alveolus is ideal for bone formation after a tooth extraction, since all the relevant factors are present to maintain immobilization and graft¹⁵. The surgical technique presented in our study, molar extraction was feasible to manufacture a bone store compatible with the same favorable factors described by Becker.

During embryonic development, the jaw bone is the second to be formed, whose origin is from the first gill arch, with a background different from the other bones of the body¹⁶. The fact of using bone grafts, allografts, xenografts and alloplastic several bones as the tibia, femur and calvaria^{2,8-11,17-19} away from the area of work in dentistry, which is why the choice of jaw for use in a model for application of biomaterials.

The tooth socket of dogs are also used for these studies^{2,11}. However, this surgical model in rabbits has offered advantages over the cost, space, storage and maintenance⁵.

Conclusion

Tooth socket of the molar of the rabbit seems to be a reliable and a feasible surgical procedure to study bone grafts.
