ABSTRACT

Growth curves models provide a visual assessment of growth as a function of time, and prediction body weight at a specific age. This study aimed at estimating tinamous growth curve using different models, and at verifying their goodness of fit. A total number 11,639 weight records from 411 birds, being 6,671 from females and 3,095 from males, was analyzed. The highest estimates of *a* parameter were obtained using Brody (BD), von Bertalanffy (VB), Gompertz (GP,) and Logistic function (LG). Adult females were 5.7% heavier than males. The highest estimates of *b* parameter were obtained in the LG, GP, BD, and VB models. The estimated *k* parameter values in decreasing order were obtained in LG, GP, VB, and BD models. The correlation between the parameters *a* and *k* showed heavier birds are less precocious than the lighter. The estimates of intercept, linear regression coefficient, quadratic regression coefficient, and differences between quadratic coefficient of functions and estimated ties of quadratic-quadratic-quadratic segmented polynomials (QQQSP) were: 31.1732±2.41339; 3.07898±0.13287; 0.02689±0.00152; -0.05566±0.00193; 0.02349±0.00107, and 57 and 145 days, respectively. The estimated predicted mean error values (PME) of VB, GP, BD, LG, and QQQSP models were, respectively, 0.8353; 0.01715; –0.6939; –2.2453; and –0.7544%. The coefficient of determination (R^2) and least square error values (MS) showed similar results. In conclusion, the VB and the QQQSP models adequately described tinamous growth. The best model to describe tinamous growth was the Gompertz model, because it presented the highest R^2 values, easiness of convergence, lower PME, and the easiness of parameter biological interpretation.

INTRODUCTION

The wide geographical dissemination, omnivorous eating habits, and hunting capacity of tinamous (*Rhynchotus rufescens*) make them attractive from the economic standpoint. Tinamous (*Rhynchotus rufescens*) belong to the Order Tinamiformes, which include a group of terrestrial fowl with gallinaceous appearance, similar to Old World partridges, *Alectoris* and *Perdix*, but geographically restricted to South America (Sick, 1985). Their reproductive period is between August and March, and one of its characteristics is a well-known peculiar peeping of the male, which start peeping one or two months before the fertile period. Breeding system is classified as polyandric (Fowler, 1986). Eggs are violet-chocolate, shiny, and have a porcelain appearance (Sick, 1985). Average egg weight is 57.70 g (Carnio *et al.*, 1999).

Tinamous raised in poultry houses similar to those used for broiler production are good candidates for domestication. They readily adapt to commercial feeds (Moro, 1996) and to routine techniques for sexing

the chicks (Moro, 1991). Nakage *et al.* (2002) determined that the optimal temperature for tinamous egg incubation is between 35.5°C and 36.5°C, and 60% relative humidity. Bruneli *et al.* (2005), studying 248 eggs, reported that tinamous chicks weigh 37.81 g at hatching, varying between 27.44 and 53.84 g. Tholon *et al.* (2003) reported a fast growth rate between 7 and 90 days of age, after which birds grow slower until slaughter age, which is around 160 days. Estimated slaughter weights and average daily weight gain were 676.3±2.0 g and 0.0235±0.0002 g/day, respectively. In studies with tinamous raised in wire-mesh aviaries in the state of Rio Grande do Sul, Menegheti *et al.* (1985) observed a weight of 663 g at 133 days of age. Recent research studies showed interesting results in terms of meat production, with a carcass yield of 74.37%, and breast yield of 36.65% (Moro *et al.*, 2006).

Therefore, the knowledge of the growth curve of tinamous and of the function that affect it is important to develop management practices to rear this species in captivity. Growth curves are mathematical models that relate body weight to age. Several mathematical models can be used to describe bird growth, and the most commonly used are those derived from the function of Richards, which includes four parameters:

$$Y_t = a(1 \pm b\ exp^{-kt})^{1/(1-m)}$$

where
Y_t is body weight at age t,
a is the asymptote value,
b is the scale parameter,
k is maturity index, and
m is the inflection parameter, which determined the function shape.

The asymptote value (a) corresponds to the estimated inflection point of the growth curve, i.e., when weight no longer changes with time, and thus, it indicates mature weight or maximal theoretical weight (Braccini Neto, 1993; Maruyama *et al.*, 1999; Mignon-Grasteau & Beaumont, 2000), as well as weight at sexual maturity. When adult weight is not reached, the parameter reflects an estimation of the weight at the last weighing (Freitas, 2005).

The scale parameter (b) does not have a biological interpretation, and it is established by the initial y and t values after birth (Braccini Neto, 1993). According to Mignon-Grasteau & Beaumont (2000) and Freitas (2005), this parameter related weight at hatching

(hatching, t =0) to asymptotic weight (t→∞).

Maturity index (k) estimates relative rate in which the asymptotic value is reached. This parameter is a logarithm function of weight, changing linearly per unit of time, and thus can be interpreted as the curve slope (Braccini Neto, 1993). It also expresses a reduction in relative growth rate (Freitas, 2005). More sigmoid curves indicate earlier growth (Kni•ztová *et al.*, 1991b), suggesting an antagonism between mature weight (a) and maturation rate (k).

The parameter "m" determines the position of the inflection point, i.e., the point in which the growth curves changes from increasing to decreasing slope, reflecting sigmoid curvature degree, with higher m values expressing a more accentuated "S" curve (Braccini Neto, 1993). According to Grossman & Bohren (1982), poultry growth curve is characteristically an asymetrical sigmoid relative to the inflection point, which is located in a non-central point of the curve. When different values are attributed to "m", different growth curve models can be obtained, such as those described below.

1) Gompertz model

The inflection parameter (m) tends to 1 in this function. The Gompertz model was originally developed to describe mortality rates in a population. It has good fitting for weight information which inflection point occurs in the beginning of growth, when approximately 35 to 40% is achieved (Braccini Neto, 1993).

2) Brody model

In this model, inflection parameter (m) is equal to zero. This function divides the growth curve in two segments: the first is designated as "growth acceleration phase", whereas the second is the "growth self-inhibition phase." The inflection point of this model joins both segments when one third of the asymptotic weight is achived.

3) von Bertalanffy model

In this function, inflection parameter (m) is equal to 2/3. The von Bertalanffy growth curve considers animal growth as the result of the opposition between anabolic and catabolic processes. The inflection point occurs when approximately 30% (8/27) of the asymptote is reached (Braccini Neto, 1993).

4) Logistic model

In this case, inflection parameter (m) is equal to 2. According to Grossman & Bohren (1982), the logistic

8

As to health management, only endo- and ectoparasite infestations were regularly checked. Tinamous houses were isolated from wild birds by wire-mesh screens, minimizing disease transmission. No vaccination program was used as, according to Sousa *et al.* (1999), these birds do not present Newcastle disease symptoms, and no symptoms of any other important diseases that affect traditional poultry production.

Eggs were collected and incubated daily. Average incubation temperature and relative humidity from 1 to 15 days of incubation were 35.5°C and 60%, respectively. On day 16, eggs were transferred to the hatcher, where the same temperature and relative humidity were applied until hatch.

In order to determine the birds' pedigree, eggs were identified with adhesive labels containing family number (pen), and egg sequential number. At hatching, birds were weighed and provisionally identified with rings of different colors in the legs, and then were transferred to the rearing pens, under similar conditions to those described above for breeders. When chicks reached approximately 90g, birds definitively identified by wing bands, containing six figure numbers, which replaces the provisional identification. Chicks were brooded during the first week of life.

Birds were weekly and individually weighed. When birds reached 250g, they were sexed by cloaca inversion, according to the procedure described by Moro (1991).

A total number of 13,164 weights from one- to 290-day-old birds was obtained. After preliminary consistency test, data on birds that were weighed less than 5 times and which parents had less than 3 known chicks were excluded. Therefore 11,639 weight data from 411 birds were used to estimate growth curves, being 6,671 from females, and 3,095 from males. These data were analyzed using least square methodology.

Brody, von Bertalanffy, logistic, Gompertz, and quadratic-quadratic-quadratic spline functions fitting of the growth curves were performed using the NLIN procedure (SAS, 1998), and the modified method of Gauss-Newton, according to Silveira Jr. *et al.* (1992). Convergence criterion was 10 exp-9, as suggested by the default software option. The equations of the growth curve models are presented below.

Logistic model $\quad Y=a*(1+b*exp(-k*age))-1$
Brody model $\quad\quad Y= a*(1-b*exp(-k*age))$
von Bertalanffy model $Y= a*(1-b*exp(-k*age))3$
Gompertz model $\quad Y=a*exp(-b*exp(-k*age))$

Q-Q-Q spline function $\quad Y = a_0 + a_1X + a_2X_2 + b_1Z_1 + b_2Z_2;$

where:
$Z_1 = 0$ $\quad\quad\quad\quad\quad$ if $X \leq K_1;$
$Z_1 = (X - K_1)^2$ $\quad\quad$ if $X > K_1;$
$Z_2 = 0$ $\quad\quad\quad\quad\quad$ if $X \leq K_2;$
$Z_2 = (X - K_2)^2$ $\quad\quad$ if $X > K_2;$

For the model equations:
Y = estimated weight at age x;
a = asymptotic weight;
b = scale parameter;
k = maturity index;
X = bird age;
a_0 = intercept;
a_1 = linear regression coefficient
a_2 = quadratic regression coefficient
K = ties between polynomial segments
b_1, b_2 = difference between function quadratic coefficients.

In order to determine segmented polynomials, and to chose initial ties, visual inspection of points of graphs depicting average weights as a function of age on the weighing day was initially performed. Successive analyses were subsequently performed, in which the initially chosen tie was changed in order to find the best tie, which was determined when the analysis presented the lowest residual sum of squares and the highest coefficient of determination (R^2), after which model parameters were estimated (Schenkel, 1989).

The analysis of Richards function derivative fitting was based on the coefficient of determination (R^2) of the models, residual mean square values (RMS), on the possibility of biological interpretation of the parameters, and easiness of convergence of parameter estimates. Mean prediction error (MPE) was obtained by the mean of all prediction errors (PE) based on each observation as a percentage of deviation between observed weight and estimated weight divided by the observed weight.

RESULTS AND DISCUSSION

Parameter estimates of growth curve models for males, females, and both sexes are shown in Table 1.

The highest estimates of parameter a (asymptotic weight) were obtained using the Brody function, followed by von Bertalanffy, Gompertz, and logistic functions for females, males, and both sexes, respectively (Table 1).

Table 1 – Estimated value means and standard errors of the tinamous growth curve parameter models von Bertalanffy, Gompertz, logistic, Brody, and quadratic-quadratic-quadratic segmented polynomial for females, males and both sexes.

Females	a	Std. error	b	Std. error	k	Std. error
von Bertalanffy	703.0	2.9445	0.7288	0.0074	0.0197	0.0002

	$b_1 = -0, 05567$		$b_2 = 0.02349$			
	$K1 = 57$		$K2 = 145$			

a = asymptotic weight; b = scale parameter; k = maturity index; a_0 = intercept; a_1 = linear regression coefficient; a_2 = quadratic. Regression coefficiente; b_1 and b_2 = difference between quadratic coefficients; K_1 and K_2 = estimated ties.

All models estimated slightly higher values of a (asymptotic weight) for females, indicating minor sexual dimorphism in mature weight. In general, female mature weight was about 5.7% higher than male mature weight.

Estimates showed low standard errors, and the logistic, Gompertz, von Bertalanffy models presented the lowest values among non-linear functions, indicating the goodness of fit of these models for estimating this parameter.

The highest estimations of parameter b for females, males, and both sexes were obtained in the logistic, Gompertz, Brody, and von Bertalanffy models, respectively. The small difference between sexes is probably due to the dependence of this parameter on the ratio between initial weight and asymptotic weight fit for each model, and thus it suffer more influence from the function used than from the difference between sexes. Low standard errors indicate a good estimation of this parameter (Table 1).

The values estimated for parameter k (maturity index) were obtained, in decreasing order, in logistic, Gompertz, von Bertalanffy, and Brody models for females, males, and both sexes, respectively. There was little difference between sexes, stressing the influence of initial weight on mature weight in tinamous. The low standard error estimates show that excellent goodness of fit for this parameter (Table 1).

The coefficients of correlation among parameters of the different models and animal classes are presented in Table 2. The correlation among parameters indicates that heavier birds are less precocious due to the antagonism between parameters a and k. However, it must be noted that the values for the correlation between a (asymptotic weight) and k (maturity index) were moderate as estimated by the studied models. Similar results were obtained by Mignon-Grasteau *et al.* (1999). Nevertheless, the correlation between these parameters varies according to species, as the growth standard is influenced by many environmental and genetic factors.

Only the Brody model presented significant correlation (p<0.05) between parameters a and b, possibly due to the higher asymptotic weight estimates as compared to the other models. Correlation between parameters b and k was high and positive in the Brody model, and intermediate to low in the other models and birds classes (Table 2).

Estimates for females, males, and both sexes of the intercept (a_0) of the quadratic-quadratic-quadratic segmented polynomial were 35.05476±4.54557; 33.58139±4.13711; and 31.01732±2.41339, respectively. Linear regression coefficient (a_1) and quadratic regression coefficient (a_2) estimates were 2.45959±0.21347; 2.58242±0.24941; 3.7898±0.13287; and 0.04099± 0.00267; 0.03525±0.00310; 0.02689±0.00152, respectively.

Table 2 – Coefficient of correlation estimates of value a (asymptotic value), b (scale parameter) and k (maturity index) of tinamous growth curve models: Logistic, von Bertalanffy, Gompertz, and Brody of females, males, both sexes, and respective levels of significance (p).
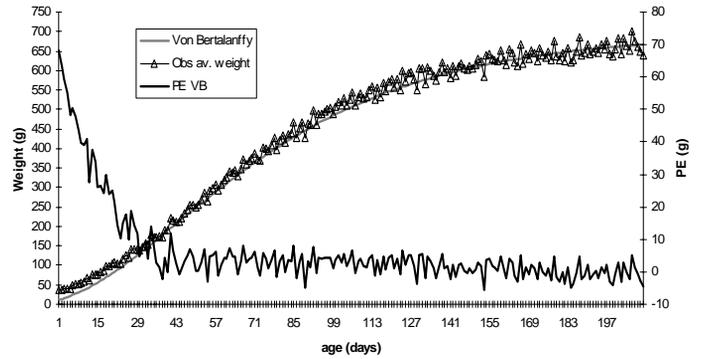

Brody		b	p	k	p

	b			0.33692	<0.0001
Males	a	-0.04628	0.6233	-0.40503	<0.0001
	b			0.43693	<0.0001

The differences between quadratic coefficients (b_1 and b_2) of the functions were:-0.06971±0.00314; -0.06147±0.00360; -0.05566±0.00193; and 0.02362 ±0.00136; 0.02481±0.00169; 0.02349±0.00107, respectively, and the estimated ties for the three bids classes were 49 and 146; 50 and 156; and 57 and 145 days of age (Table 1).

Small differences were observed during the first growth phase between sexes. Growth pattern was different only after secondary sexual development (around 5 months of age). Male initial weight was lower than that of females, but their growth pattern was similar. Males were more precocious as compared to females, confirming the trend observed in previous functions relative to mature weight and sexual precocity.

Based on the obtained parameters, growth curves were estimated for both sexes using von Bertalanffy, Gompertz, Brody, logistic, and quadratic-quadratic-quadratic segmented polynomial models (Figures 1, 2, 3, 4 and 5).

The von Bertalanffy model underestimated 1 to 29-day-old bird weight, and overestimated weights after 210 days of age (Figure 1). The Gompertz model

Figure 1 – Estimates of prediction error (PE), observed and fitted weight of tinamous (*Rhynchotus rufescens*), by the von Bertalanffy model.

Figure 2 – Estimates of prediction error (PE), observed and fitted weight of tinamous (*Rhynchotus rufescens*), by the Gompertz model.

Figure 3 – Estimates of prediction error (PE), observed and fitted weight of tinamous (*Rhynchotus rufescens*), by the Brody model.

Figure 4 – Estimates of prediction error (PE), observed and fitted weight of tinamous (*Rhynchotus rufescens*), by the logistic model.

Figure 5 – Estimates of prediction error (PE), observed and fitted weight of tinamous (*Rhynchotus rufescens*), by the quadratic-quadratic-quadratic segmented polynomial model.

presented excellent goodness of fit until 210 days of age, with slight underestimation of weight from 1 to 43 days of age (Figure 2). The Brody model showed lack of fit for the first 15 days of age, underestimating initial weights, and overestimating final weights after 30 weeks of age, as this model considers that the self-inhibition phase starts when the bird hatches (Figure 3), i.e., the inflection point occurs at hatching. The logistic model presented lack of fit in the first 70 days of age, overestimating initial weight, and was the only function to present such a behavior (Figure 4). Q-Q-Q segmented polynomial presented excellent goodness of fit for all categories, but overestimated initial weights until 29 days of age (Figure 5).

In all analyzed models, there were some fitting problems in the first and the last weeks of life, probably due to the fact that the birds lost weight during the first week of life, as they do not feed during this phase, and due to the lower number of birds weighed at later ages caused by mortality throughout the analyzed period.

Mean prediction error (MPE) estimates obtained from the mean of prediction errors estimated for each phase allow a better assessment of goodness of fit of the models. Estimates of mean, minimal, and maximal prediction error females, males, and both sexes are shown in Table 3.

Mean prediction error (MPE) estimates, in grams, in the von Bertalanffy model for both sexes, females, and males were, respectively, 4.2510; 0.7473; and 0.8353, indicating that, in general, this function underestimated the observed values. For the Gompertz model, these estimates were 0.0785; −0.3441; and 0.1715, overestimating, in general, values observed in females, and overestimating values observed in the two other classes. The Brody model presented MPE estimates of −0.9458; -1.1297; and −0.6939, overestimating values observed in the three classes. The logistic function presented MPE estimates of −1.7774; -2.4271; and −2.2457, overestimating, in general, the observed values. Q-Q-Q segmented polynomial presented MPE estimates of −0.3796; 1.1706; and −0.7544, underestimating, in general, values observed in females and overestimating, in general, values obtained from males and both sexes.

The quadratic-quadratic-quadratic segmented polynomial and the Gompertz model presented similar trends as to growth function fit, with the highest PE at 245 and 242 days of age, respectively. The other models had worse fit at one and five days of age, indicating modeling difficulties in the first days, probably due to weight loss during this phase.

As to minimal PE values, the studied models did not present consistent similarities in terms of fit. There was age variation as a function of sex and used model (Table 3).

Table 3 – Estimates of prediction errors (PE), mean prediction errors (MPE), and minimal (Min) and maximal (Max) prediction errors, in grams for females, males, and both sexes (Both), using von Bertalanffy (VB), Gompertz (GP), Brody (BD), logistic (LG), and quadratic-quadratic-quadratic segmented polynomial (QQQSP) models.
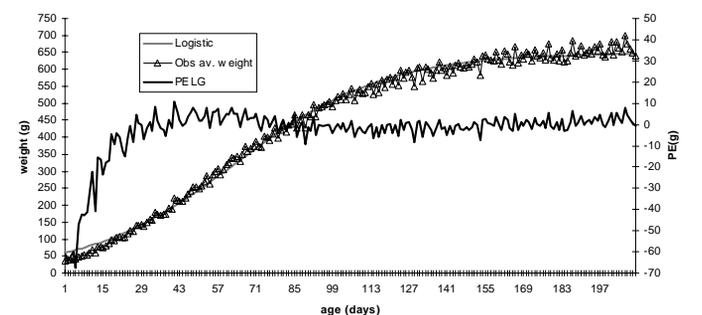

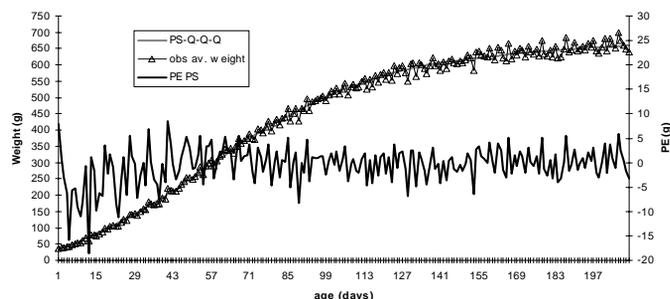

Both	PE VB	PE GP	PE BD	PE LG	PE QQQSP

Gompertz	3477.3	0.9211	14	7
Logistic	3546.1	0.9196	4	2
Brody	4171.3	0.9054	9	43
QQQSP	3472.2	0.9213	-	-
Both	**RMS**	**R^2**	**N. it**	**N. birds**
von Bertalanffy	4782.7	0.9009	39	38
Gompertz	4718.4	0.9023	14	17
Logistic	4814.7	0.9003	3	7
Brody	5431.7	0.8875	12	125
QQQSP	4720.7	0.9023	-	-

The Gompertz and Q-Q-Q segmented polynomial models presented the lowest RMS values (4718.4 and 4720.7, respectively) and the highest R^2 (0.9023 for both) values, indicating better goodness of fit of these models.

Another criterion used to evaluate goodness of fit was easiness of convergence to obtain parameters. Table 4 shows the number of iteractions needed for convergence, and the number of animals which growth curve parameters were not possible to estimate. The Q-Q-Q segmented polynomial model was not included, as it depends on previous knowledge of the curve for initial estimates of the ties.

The number of iteractions needed for convergence may not be the best indicator of easiness of convergence, as it depends on the initial values used in the iteration process; however, the number of birds which growth curve parameters were not possible to estimate may suggest faster data analysis. The Brody model presented the highest number of birds with no parameter estimates, which was probably due to lack of fit during initial ages, a period where the highest number of weight data are concentrated.

It must be noted that, although the Q-Q-Q segmented polynomial model presented excellent results as to goodness of fit, it did not provide parameters similar to the other studied models, and also depends on previous experience for the estimation of parameters, such as the determination of initial ties.

Using the von Bertalanffy model to describe tinamous growth from hatching to 230 days of age, Moro (1991) found overestimated weight after 85 days of age for females. This function did not provide goodness of fit for the growth of males, which weights were overestimated from 1 to six weeks of age and from 20 to 30 weeks of age, and underestimated in the interval between 8 and 17 weeks of age. Despite fitting deficiencies, the von Bertalanffy model was the only one that allowed tinamous weight modeling. Different results were reported by Menegheti *et al.* (1985), who found that the logistic model was the best to describe tinamous growth. These authors observed initial body weight stabilization at 19 weeks of age (663 g). These studies were carried out with birds reared on dirt floor. Tholon *et al.* (2003) used 4,833 weight data of tinamous of both sexes, and observed that Gompertz and von Bertalanffy functions best described growth. In that study, a quadratic-quadratic segmented polynomial was used, with the tie at 35 days of age, to model the growth curve, but the fitting criteria for this function were lower than those obtained using the above mentioned functions.

Growth curve parameters of animals belonging to the same species and reared in different environments must be compared with caution, as rearing conditions have a strong influence on performance. In addition, comparisons among results obtained with birds belonging to different species, despite possible, must be avoided, as growth patterns of each species present estimates with very different values. The literature reviewed for the present study mostly refer to other species, and therefore, discuss growth patterns of species that present different biological aspects in terms of growth.

CONCLUSIONS

The von Bertalanffy and the quadratic-quadratic-quadratic segmented polynomial were adequate to describe tinamous growth.

The model that best described tinamous growth was the Gompertz model, as it presents high R^2 values, easiness of convergence, lower MPE, and allows biological interpretation of its parameters.

The Brody and the logistic models presented lower goodness of fit, with the highest RMS and MSE, and the lowest R^2 values due to fitting problems in the initial phase of growth.
