

ENTOMOPHTHORAMYCOSIS BY *Conidiobolus coronatus*. REPORT OF A CASE SUCCESSFULLY TREATED WITH THE COMBINATION OF ITRACONAZOLE AND FLUCONAZOLE

Antonio Carlos Francesconi do VALLE(1), Bodo WANKE(2), Márcia dos Santos LAZÉRA(2), Paulo Cezar Fialho MONTEIRO(2) & Maria de Lourdes VIEGAS(3)

SUMMARY

Rhinoentomophthoramycosis caused by *Conidiobolus coronatus* in a 61-year old woman was unsuccessfully treated during 8 years with all the antifungals available in the Brazilian market, including potassium iodide for 1 month, sulfamethoxazole plus trimethoprim for 2 months, amphotericin B, total dose of 1130 mg, cetoconazole, 400 mg/day for 6 months, fluconazole, 200 mg/day, for at least 2 months and, itraconazole, 400 mg/day for 2 months, followed by 200 mg/day for 4 more months. Complete clinical and mycological cure was achieved using itraconazole 400 mg/day in association with fluconazole 200 mg/day during 24 months. After cure she was submitted to plastic surgery to repair her facial deformation. Today she remains clinically and mycologically cured after 59/60 months (5 years!) without any specific antifungal. We thus suggest the use of the combination of itraconazole and fluconazole as an additional option for the treatment of this mycosis.

KEYWORDS: Entomophthoramycosis; Zygomycosis; Combination triazole treatment; Rhinoentomophthoramycosis.

INTRODUCTION

Entomophthoramycosis affects individuals with an apparently intact immunological status and occurs primarily in tropical areas. Two zygomycetes belonging to the order Entomophthorales are the etiologic agents of subcutaneous entomophthoramycosis: *Basidiobolus ranarum* (= *B. haptosporus*) and *Conidiobolus coronatus*^{3,7}. *C. coronatus* has already been isolated from soil samples, rotting plant matter, insects, and the gastrointestinal contents of lizards and frogs, especially in tropical and subtropical regions¹¹.

Infection by *B. ranarum* manifests itself as a subcutaneous tumefaction located on the trunk, buttocks, or proximal portion of the limbs. Invasion of the abdominal and thoracic cavities by extension of the subcutaneous tumor mass has been reported. More recently there have been case reports with frankly visceral manifestations, with gastric and intestinal tumoral lesions, presenting as acute abdomen^{3,7}.

Lesions by *C. coronatus* begin as infiltration of the nasal mucosa and submucosa, extending to the adjacent tissues of the paranasal sinuses, nasal dorsum, upper lip, and face, with no delimitation to their growth. The tumefaction, with a nodular or polipose infiltrative appearance, is covered by erythematous, hard skin, displaying continuity with the underlying tissues. The clinical manifestations result from the expansion of the tumor mass. Because of its initially central facial presentation affecting the nose first, the disease is also known as rhinoentomo-

phthoramycosis. In the more advanced cases, the lesions can also affect the nasopharynx, oropharynx, palate, cervical region, and even the mediastinum^{3,7}. The first mycologically proven cases in humans were described independently and simultaneously in 1965 in Jamaica⁴ and Africa¹².

Cases of rhinoentomophthoramycosis have been described in Africa, Asia, and the Americas, ranging between the tropics of Cancer and Capricorn. The disease is essentially chronic, evolving over the course of years. No incubation period or cases of spontaneous involution are known. Diagnosis is made by clinical, histopathological, and mycological examination².

According to the medical literature, treatment can be applied with satisfactory results using potassium iodide, amphotericin B, and cetoconazole. However, the literature provides little information on long-term follow-up and/or relapses. We present a case of rhinoentomophthoramycosis caused by *C. coronatus* in which all the available antifungals, including itraconazole and fluconazole, had been used singly without success. However, the patient evolved to complete cure after long-term combination therapy with these two triazoles.

CASE REPORT

A 61 year-old white woman, domestic, living in the state of Maranhão, northeast Brazil, presented a history of a disease lasting 8

years (Fig. 1). During this period she was examined at several hospitals, and after obtaining the diagnosis of entomophthoramycosis based on clinical, mycological and histopathological findings, treated with the following drugs:

- potassium iodide for 1 month, with worsening of the lesions;
- sulfamethoxazole plus trimethoprim for 2 months, with no therapeutic response;
- amphotericin B, total dose of 1130 mg, with partial improvement;
- cetoconazole, 400 mg/day for 6 months, with a favorable clinical response. Treatment was interrupted because the patient could not afford the medication. After a relapse, she resumed use of this medication, with no therapeutic response;
- fluconazole, 200 mg/day, for at least 2 months, with no therapeutic response;

Fig. 1 - Aspect of the patient at admission.

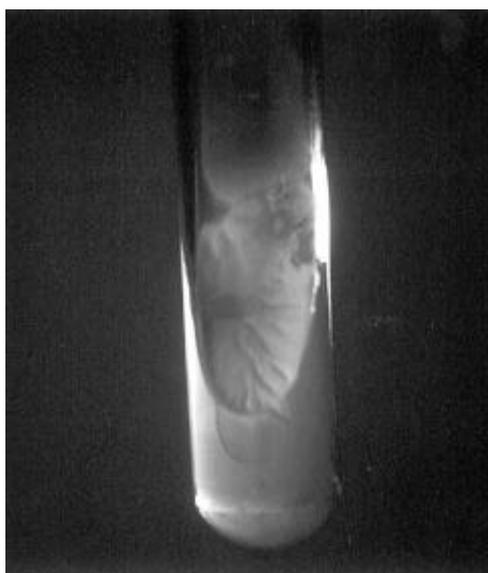

Fig. 2a - Culture of *Conidiobolus coronatus*.

- itraconazole, 400 mg/day for 2 months, followed by 200 mg/day for 4 more months, with no therapeutic response.

The patient was referred to the Evandro Chagas Hospital at the Oswaldo Cruz Foundation in Rio de Janeiro for specific treatment, where the diagnosis of rhinoentomophthoramycosis by *C. coronatus* was confirmed on clinical, histopathological, and mycological examination (Fig. 2a and 2b). At the beginning of April 28, 1993, due to the lack of other treatment options, we initiated combined oral fluconazole 200 mg/day and itraconazole 400 mg/day until April 1995. The patient evolved to clinical and mycological cure in 3 months (Fig. 3). Throughout treatment she was monitored every 2 months with clinical and mycological examination, complete blood count, and blood biochemical tests and presented no side effects or signs of toxicity. After the specific clinical treatment during 24 months, restorative surgery was performed to correct sequelae (Fig. 4). At the last clinical assessment, in March 2000, the patient had been off medication for 59 months and remained clinically cured.

DISCUSSION

Entomophthoramycosis occurs sporadically in tropical regions of Asia, Africa, and the Americas. The disease is caused by fungi living saprophytically in organic debris in the environment. So far only few cases of rhinoentomophthoramycosis caused by *C. coronatus* were reported. In Brazil, the first case was described by ANDRADE *et al.* in 1967¹, only two years after the first reports on this mycosis in cases from Africa and Jamaica. Later on, cases were reported from the states of the North^{9,10} and more frequently from the Northeast of Brazil (states of Bahia, Piauí, Maranhão, and Sergipe)^{1,2,6,8,14,17}. In the present case the patient was a native of the state of Maranhão, reinforcing the Northeast as the main focus of this mycosis in Brazil.

Clinical and histopathological findings are quite suggestive, but definitive diagnosis is only possible by isolating and identifying the fungus in appropriate culture media. Clinically, the differential diagnosis

should consider scleroma, rhinosporidiosis, and benign and malignant tumors of the nasal cavity⁸. Histopathological examination shows an inflammatory granulomatous reaction, with a predominantly mononuclear infiltrate consisting of lymphocytes, histiocytes, and some multinucleated giant cells, along with plasma cells and eosinophils. The central portion shows broad, thin-walled, irregular branching hyphae, frequently approaching right angles. These hyphae do not usually display septa and are surrounded by a peculiar eosinophilic mass (the Splendore-Hoeppli phenomenon). The appearance is similar to that of subcutaneous entomophthoramycosis caused by *B. ranarum*. In our clinical case the diagnosis was based on clinical and histopathological examination confirmed by mycological identification of *C. coronatus*.

According to the literature, treatment of rhinoentomophthoramycosis has been performed successfully with potassium iodide³, combination sulfamethoxazole-trimethoprim⁵, amphotericin B^{3,5}, and cetoconazole^{8,17}. All of these drugs were used unsuccessfully in the present case. Itraconazole and fluconazole, broad-spectrum triazolic derivative antifungals were used effectively against various other mycoses, had also been used singly to treat the patient, initially producing regression of the lesions, but with reactivation of the infection shortly afterwards.

All the antifungals available in Brazil in 1993 failed to cure the patient. Saperconazole, a new broad-spectrum imidazolic derivative, also was not available at that time because it has been removed from the market due to the development of tumors in laboratory animals. For lack of other options and based on reports of the successful use of multidrug therapy in various infectious diseases, we used a combination of itraconazole and fluconazole obtaining an excellent therapeutic response. In fact, the response was similar to that found by other authors in treating other mycoses with this combination therapy^{13,15,16}. No side effects or

drug-related toxicity were observed. We thus suggest the use of the combination of itraconazole and fluconazole as an additional option for the treatment of this mycosis. Possibly this may be also valid for other disseminated or opportunistic mycoses, especially in cases following treatment failure with the classic drug regimens.

Itraconazole and fluconazole are triazoles with similar mechanisms, acting especially on the fungal cell wall's cytochrome p450. However, the underlying mechanism of a possible synergism between both drugs is so far unknown. We didn't find reports of antagonism between these two drugs.

Due to the lack of criteria for control of biological cure in this mycosis and the small number of cases reported in the literature, treatment is somewhat empirical, since the precise dosage and duration of treatment are unknown. In our case, as in others reported in the literature, there had been an initially favorable response to certain drugs, but their removal, perhaps too early, had led to *in vivo* resistance. Therefore, even with a clinical cure after 3 months, we maintained this combination drug therapy for over 19 months. There is a report of cure in this mycosis following surgical treatment, but in our case surgery was performed to correct sequelae, and the successive histopathological and mycological tests of the operatory specimens were negative.

RESUMO

Entomofatoramicose por *Conidiobolus coronatus*. Relato de um caso tratado com a associação de itraconazol com fluconazol

É relatado um caso de rinoentomofatoramicose por *Conidiobolus coronatus* em mulher de 61 anos submetida a tratamento com todos os antifúngicos disponíveis no mercado brasileiro, durante 8 anos, sem sucesso, incluindo iodeto de potássio por 1 mês, sulfametoxazol associado ao trimetoprim por 2 meses, anfotericina B em dose total de 1130 mg, cetoconazol, 400 mg/dia por 6 meses, fluconazol, 200 mg/dia, por pelo menos 2 meses, e itraconazol, 400 mg/dia, por 2 meses, seguido de 200 mg/dia por mais 4 meses. A cura clínica e micológica completa foi obtida com a associação de itraconazol 400mg/dia com fluconazol 200 mg/dia, durante 24 meses. Após a cura a paciente foi submetida a cirurgia restauradora. Atualmente a paciente encontra-se há 59 meses sem medicação específica permanecendo clínica e micologicamente curada.
