Effects of a nursing intervention in the control of symptoms in patients with fibromyalgia. Case report

Efetos de uma intervenção de enfermagem no controle de sintomas de pacientes com fibromialgia. Relato de caso

ABSTRACT

BACKGROUND AND OBJECTIVES: Fibromyalgia is a non-inflammatory rheumatic syndrome, characterized by diffuse chronic musculoskeletal pain, usually accompanied by other symptoms not related to the locomotor system such as depression, fatigue, cognitive alterations, impaired sleep quality, and headache. This study aimed to evaluate the impact of a nursing intervention in the control of pain and depressive symptoms of patients with fibromyalgia.

METHODS: A quasi-experimental study conducted through the electronic database review of a private chronic patients monitoring service. The sample included 353 patients with fibromyalgia who were attended in the period from 2014 to 2017. The nursing intervention included a home visit and the application of educational strategies over the telephone for 6 months. Participants were assessed using the verbal numerical rating scale and the Patient Health Questionnaire scale. The comparison between the continuous variables was performed by the t-paired test, and the comparison between the categorical variables was performed using the McNemar-Bowker test. The level of significance was set at p<0.05.

RESULTS: Nursing intervention promoted a significant reduction in the average pain intensity (p=0.001) after the intervention. The reduction in the average depression score, however, was not significant (p=0.093), but the intervention significantly reduced the cases of moderate and very severe depression (p=0.01).

CONCLUSION: Nursing intervention by telephone showed a positive impact on pain control and reduction of depressive symptoms in patients with fibromyalgia.

Keywords: Depression, Fibromyalgia, Nursing, Pain.

RESUMO

JUSTIFICATIVA E OBJETIVOS: A fibromialgia é uma síndrome reumatológica não inflamatória, caracterizada por dor musculosquelética crônica e difusa, geralmente acompanhada por outros sintomas não relacionados ao aparelho locomotor como depressão, fadiga, alterações cognitivas, qualidade de sono prejudicada e cefaleia. O objetivo deste estudo foi avaliar o impacto de uma intervenção de enfermagem no controle da dor e nos sintomas depressivos de pacientes com fibromialgia.

MÉTODOS: Estudo quase-experimental realizado por meio da revisão de banco de dados eletrônico de um serviço privado de monitoramento de pacientes crônicos. A amostra incluiu 353 pacientes com fibromialgia, atendidos no período de 2014 a 2017. A intervenção de enfermagem incluiu uma visita domiciliar e a aplicação de estratégias educativas por telefone ao longo de 6 meses. Os participantes foram avaliados por meio da escala numérica verbal de dor e pela escala Patient Health Questionnaire. A comparação entre as variáveis contínuas foi realizada pelo teste t-pareado e a comparação entre as variáveis categóricas foi realizada por meio do teste McNemar-Bowker. O nível de significância foi estabelecido com valor de p<0,05.

RESULTADOS: A intervenção de enfermagem promoveu redução significativa na intensidade média da dor (p<0,001) após a intervenção. A redução do escore médio de depressão, no entanto, não foi significativa (p=0,093), mas a intervenção reduziu significativamente os casos de depressão moderada e muito grave (p=0,01).

CONCLUSÃO: A intervenção de enfermagem por telefone demonstrou impacto positivo no controle da dor e na redução dos sintomas depressivos de pacientes com fibromialgia.

Descritores: Depressão, Dor, Enfermagem, Fibromialgia.

INTRODUCTION

Fibromyalgia (FM) is a non-inflammatory rheumatic syndrome, characterized by chronic and diffuse musculoskeletal pain, usually accompanied by other symptoms not related to the locomotor system such as fatigue, cognitive alterations, impaired sleep quality, and headache. Among the main symptoms, pain is the main clinical manifestation presented, causing the diagnosis and treatment to be sought. Another factor that stands out is the presence of depressive symptoms in patients with FM, indicating the relevance of approaching psychic aspects during treatment.
Interdisciplinary treatment for fibromyalgia is recommended, including a pharmacological and non-pharmacological approach, which should include educational strategies and active participation of the patient in the control of the disease\(^2,3\). Therefore, monitoring associated with the use of educational strategies can improve treatment outcomes, reduce pain, physical limitations and costs caused by these diseases\(^4\).

In 2011, the Ministry of Health developed the Strategic Action Plan for Coping with Chronic Noncommunicable Diseases (CNCD) aimed at prevention and control through the strategic axis of surveillance, information, evaluation, and monitoring\(^6\). In this context, telephone interventions can be an alternative strategy with high coverage and can be used exclusively or complementarily in education and health promotion, especially in patients with chronic diseases\(^5\).

The nurse is a trained professional to apply educational interventions, informing the patients about the disease, the treatment and the handling of symptoms, and can positively impact the quality of life.

Considering this scenario, this study aimed to evaluate the impact of the nursing intervention on pain control and on the depressive symptoms of patients with FM.

**METHODS**

A quasi-experimental study with retrospective data collection, of the case series type, performed through the electronic database review, which included 353 patients attended from January 2014 to March 2017. The population was composed of patients with FM attended by a private monitoring service for chronic patients in a program called “Articulation,” aimed at monitoring patients with FM and Rheumatoid Arthritis (RA). Patients with FM were diagnosed by the attending doctor using the American College of Rheumatology (ACR) 2010 criteria and referred to participate in the “Articulation” Program. All those who agreed to participate were included in the study. The convenience sample consisted of 353 patients with FM.

The nursing intervention observed in this study has national coverage and monitors patients by telephone, in addition to a face-to-face visit or web contact (if there is no visitor in the patient’s region) for the initial evaluation. The “Articulation” program consists of two stages: 1) Intervention and 2) Quarterly self-control, and aims to improve treatment compliance and results of patients with FM and RA.

The flow begins with referral of patients from a health plan to the chronic patient monitoring company, where the evaluator makes the initial welcome contact, evaluates the eligibility criteria, and invites to participate in the program. When the patient meets the inclusion criteria, the evaluator triggers a professional for a home visit, who performs the initial evaluation and definition of the level of care and monitoring.

The next step is to send a letter of invitation to the patient and, starting from that, the 6-month Intervention phase begins, in which nurses perform at least one monthly telephone contact for monitoring and orientation, aiming at the stabilization of the disease. The guidelines for the nursing intervention phase include information on the disease and treatment, the importance of control exams, and recommendations for physical exercise. After this stage, the patient moves to the Quarterly Self-Control phase, in which the nurse comes in contact every 3 months to evaluate the health status of these patients. If there is no stabilization of the disease at the end of 6 months (Intervention phase), the patient remains with monthly monitoring for another six months, being re-evaluated at the end of this period to define the type of follow-up.

Demographic and clinical variables analyzed were: gender, age, education, state of residence, type of monitoring, symptoms, pain intensity, drugs in use, adherence to treatment and risk score for depression.

**Measuring instruments used in monitoring**

The intensity of pain was evaluated by verbal numerical rating scale (VNRS) ranging from zero to 10, with “zero” being no pain and “10” being the worst pain imaginable, later classified as mild pain (1 to 3), moderate (4 to 6) and severe (7 to 10).

The risk of depression was evaluated using the Patient Health Questionnaire (PHQ-9) scale, translated and validated for the Portuguese language, already used in the routine monitoring of the monitoring service with version available online\(^6\).

The PHQ-9 scale is an instrument originally designed to identify the risk of depression in the general population, but it can also be used to indicate the severity of depressive symptoms\(^6\). It is a quick application instrument, consisting of 9 items that deal with depressed mood, anhedonia (loss of interest or pleasure in doing things), problems with sleep, tiredness or lack of energy, change in appetite or weight, feeling of guilt or uselessness, trouble concentrating, feeling slow or restless, and suicidal thoughts\(^6\). Each symptom is evaluated according to the Likert scale, where 0= “None”, 1= “Multiple days”, 2= “More than half the days” and 3= “Almost every day”\(^7\). The total score can be classified into categories that indicate the risk of depression: 0=absent; 1 to 5=mild; 6 to 14=moderate; 15 to 19=severe; 20 or more=very severe\(^8\).

This project followed the recommendations of Resolution No. 510/2016 of the National Health Council (NHC)\(^9\), according to which there is no need for evaluation by the Research Ethics Committee for studies that use databases with aggregated information without the possibility of individual identification of participants.

**Statistical analysis**

The data were included in the Microsoft Excel\(^\text{®}\) Program Sheet and analyzed through the Statistical Package for the Social Sciences (SPSS), in which descriptive and inferential analyzes were performed considering only the existing data for each item analyzed. Continuous variables were expressed as mean, standard deviation and median, and the categorical variables were described in numbers and percentages. The comparison between the continuous variables was performed through the t-paired test, and the comparison between the categorical variables was performed using the McNemar-Bowker test. The level of significance was set at p<0.05.
RESULTS

Data from 353 patients with FM were analyzed. Females accounted for 96%, with a mean age of 51 years (SD=12) and 54.6% had higher education. Regarding the origin, there was a greater number of participants from the states of São Paulo (59.9%), Bahia (10.5%) and Rio de Janeiro (9.9%). Among the patients evaluated, 63.6% were in the Monthly Intervention phase, and 36.4% were in Quarterly Self-Control (Table 1).

At the beginning of the follow-up, 43% of the participants had persistent and generalized pain, 39.6% had controlled symptoms and 11.5% referred to fatigue. Regarding pharmacological treatment, 53.8% used antidepressants, 49.5% analgesics, and 9.2% benzodiazepines. Pain intensity data were compared before and after the monthly intervention, and there was a significant reduction in mean pain intensity (p <0.001). The reduction of the depression score was not significant (p = 0.093), as can be observed in table 2.

The comparison of pain by categories before and after the Intervention showed a significant reduction of cases of intense pain and an increase of cases of absent, mild and moderate pain (p>0.001), according to figure 1.

Concerning the risk of depression, a comparison of the scores by categories showed that the intervention reduced the cases of mild, moderate and very severe depression and increased the cases without risk of depression and with severe depression (p = 0.01), according to the figure 2.

DISCUSSION

Similar to other national studies, this study found a prevalence of FM in women with a mean age of 52 years⁹. Regarding the educational level, there was a predominance of patients with higher education, which does not reflect the Brazilian reality, but can be explained by the fact that the study population is part of a private health plan that offers nursing intervention and continuous monitoring of these patients.

The comparison of mean pain intensity before and after the intervention showed a significant reduction in pain (from 5.4 to 4.3). The mean pain intensity observed in this study was lower than in other studies, which found a mean pain around eight⁷,⁹ at the Outpatient Rheumatology Clinic of the Federal University of Paraná (UFPR) and at the Rheumatology Service of the University Hospital of Recife.¹⁰,¹¹

With regard to depressive symptoms, the reduction of the mean depression score after the nursing intervention was not significant (p = 0.093). However, the comparison of depression scores
according to categories showed a significant reduction in cases of mild, moderate and very severe risk and an increase in cases of absent and severe risk, indicating an improvement in depressive symptoms for most of the study participants. Studies have shown that depression is frequent in patients with FM\textsuperscript{12-14}, requiring identification and intervention in these cases, since these patients may demonstrate worsening of physical symptoms when they present untreated psychological disorders\textsuperscript{15}. On the other hand, a study conducted in 2013 showed that 51% of the participants believed that depression and anxiety were the factors that caused FM\textsuperscript{16}. However, no scientific data were found to confirm this relationship.

Regarding pharmacological treatment, 53.8% of the patients used antidepressants, a proportion that may be considered low, since international recommendations for the treatment of FM indicate antidepressants as the first treatment line\textsuperscript{9}. The nursing intervention analyzed in this study is in line with the recommendations of the Brazilian Consensus for the treatment of FM, which reaffirms the importance of guidelines and programs for self-control of pain\textsuperscript{17-19}.

Therefore, nursing intervention with telephone monitoring was an effective strategy to improve treatment outcomes in patients with FM, confirming the efficacy of the recommendations of the national and international consensus for the treatment of this syndrome.

CONCLUSION

The nursing intervention showed a positive impact on the control of pain and on the reduction of the depressive symptoms in patients with fibromyalgia.
